The environmental activist association **Greenpeace** also issued a report in July 2001, entitled, *Out of Fashion Moving Beyond Toxic Cleaners.* This report urged the EPA to classify perc as a probable human carcinogen. The report claimed that up to 266 workers' cancer deaths in New York, Chicago, Detroit, and San Francisco were linked to perc.

As of 2002, the dry cleaning industry estimates that approximately 36,000 dry cleaning establishments exist across the United States, with about 200,000 people employed in the industry. Perc is used in at least 85% of dry cleaning shops as the primary solvent. This means that if perc is found to be a cancer causing chemical, many people, including both workers in and people who live near dry cleaning facilities, may be adversely affected.

Dry deposition

A process that removes airborne materials from the **atmosphere** and deposits them on a surface. Dry deposition includes the settling or falling-out of particles due to the

influence of gravity. It also includes the deposition of gas-phase compounds and particles too small to be affected by gravity. These materials may be deposited on surfaces due to their solubility with the surface or due to other physical and chemical attractions. Airborne contaminants are removed by both wet deposition, such as rainfall scavenging, and by dry deposition. The sum of wet and dry deposition is called total deposition. Deposition processes are the most important way contaminants such as acidic sulfur compounds are removed from the atmosphere; they are also important because deposition processes transfer contaminants to aquatic and terrestrial ecosystems. Cross-media transfers, such as transfers from air to water, can have adverse environmental impacts, and an example of this is how dry deposition of sulfur and **nitrogen** compounds can acidify poorly buffered lakes. *See also* Acid rain; Nitrogen cycle; Sulfur cycle

Dryland farming

Dryland farming is the practice cultivating crops without **irrigation** (rainfed agriculture). In the United States, the term usually refers to crop production in low-rainfall areas without irrigation, using moisture-conserving techniques such as mulches and fallowing. Non-irrigated farming is practiced in the Great Plains, inter-mountain, and Pacific regions of the country, or areas west of the 23.5 in (600 mm) annual precipitation line, where native vegetation was short **prairie** grass. In some parts of the world dryland farming means all rainfed agriculture.

In the western United States, dryland farming has often resulted in severe or moderate wind **erosion**. Alternating seasons of fallow and planting has left the land susceptible to both wind and water erosion. High demand for a crop sometimes resulted in cultivating lands not suitable for long-time farming, degrading the **soil** measurably.

Conservation tillage, leaving all or most of the previous crop residues on the surface, decreases erosion and conserves water. Methods used are stubble **mulch**, mulch, and ecofallow. In the wetter parts of the Great Plains, fallowing land has given over to annual cropping, or three-year rotations with one year of fallow. *See also* Arable land; Desertification; Erosion; Soil; Tilth

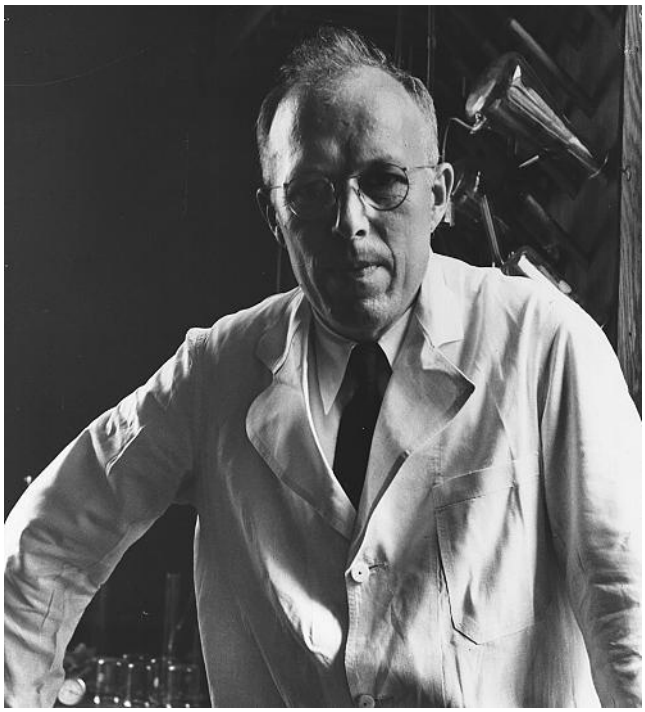
René Jules Dubos (1901 – 1982)

French/American microbiologist, ecologist, and writer

Dubos, a French-born microbiologist, spent most of his career as a researcher and teacher at Rockefeller University in New York state. His pioneering work in microbiology, such as isolating the anti-bacterial substance *gramicidin* from a **soil** organism and showing the feasibility of obtaining germ-fighting drugs from **microbes**, led to the development of antibiotics.

Nevertheless, most people know Dubos as a writer. Dubos's books centered on how humans relate to their surroundings, books informed by what he described as "the main intellectual attitude that has governed all aspects of my professional life...to study things, from microbes to man, not *per se* but in their complex relationships." That pervasive intellectual stance, carried throughout his research and writing, reflected what *Saturday Review* called "one of the best-formed and best-integrated minds in contemporary civilization."



A related theme was Dubos's conviction that "the total environment" played a role in human disease. By total **environment**, he meant "the sum of the facts which are not only physical and social conditions but emotional conditions as well." Though not a medical doctor, he became an expert on disease, especially tuberculosis, and headed Rockefeller's clinical department on that disease for several years.

"Despairing optimism" also pervaded Dubos's human-environment writings, his own title for a column he wrote for *The American Scholar*, beginning in 1970. *Time* magazine even labeled him the "prophet of optimism:" "My life philosophy is based upon a faith in the immense resiliency of nature," he once commented.

Dubos held a lifelong belief that a constantly changing environment meant organisms, including humans, had to adapt constantly to keep up, survive, and prosper. But he worried that humans were too good at adapting, resulting in both his optimism and his despair: "Life in the technologized environment seems to prove that [humans] can become adapted to starless skies, treeless avenues, shapeless buildings, tasteless bread, joyless celebrations, spiritless pleasures—to a life without reverence for the past, love for the present, or poetical anticipations of the future." He stated that "the belief that we can manage the earth may be the ultimate expression of human conceit," but insisted that **nature** is not always right and even that humankind often improves on nature. As Thomas Berry suggested, "Dubos sought to reconcile the existing technological order and the planet's survival through the **resilience** of nature and changes in human consciousness."

Ducks Unlimited

Ducks Unlimited (DU) is an international (United States, Canada, Mexico, New Zealand, and **Australia**), membership organization founded during the depression years in the United States by a group of sportsmen interested in waterfowl **conservation**. DU was incorporated in early 1937, and DU (Canada) was established later that spring. The organization was established to preserve and maintain waterfowl populations through **habitat** protection and development, primarily to provide game for sport **hunting**. During the **Dust Bowl** of the 1930s, the founding members of DU recognized that most of the continental waterfowl populations were maintained by breeding habitat in the **wetlands** of Canada's southern prairies in Saskatchewan, Manitoba, and Alberta. The organizers established DU Canada and used their resources to protect the Canadian **prairie** breeding grounds. Cross-border funding has since been a fundamental component of DU's operation, although in recent years funds also have been directed to the northern American prairie states. In 1974 Ducks Unlimited de Mexico was established to restore and maintain wetlands south of the U.S.-Mexican border where many waterfowl spend the winter months.

Throughout most of its existence, DU has funded habitat restoration projects and worked with landowners to provide water management benefits on farmlands. But, from its inception DU has been subject to criticism. Early opponents characterized it as an American intrusion into Canada to secure hunting areas. More recently, critics have suggested that DU defines waterfowl habitat too narrowly, excluding upland areas where many ducks and geese nest. The group plans to broaden its focus to encompass preservation of these upland breeding and nesting areas. Since many of these areas are found on private land, DU also plans to expand its cooperative programs with farmers and ranchers. Most commonly, however, DU is criticized for placing the interests of waterfowl hunters above **wildlife management** concerns. The organization does allow duck hunting on its preserves.

Following the fundamental principle of "users pay," duck hunters still provide the majority of DU's funding. For that reason DU has not addressed some issues that have a serious effect on continental waterfowl populations. The combination of illegal hunting and liberal bag limits is blamed by some for the continued decline in waterfowl numbers. DU has not addressed this issue, preferring to leave management issues to government agencies in the United States and Canada, while focusing on habitat preservation and restoration. Critics of DU suggest that the organization will not act on population matters and risk offending the hunters who provide their financial support.

In North America DU has expanded its scope and activities to address ecological and **land use** problems through the work of the North American Waterfowl Management Plan (NAWMP) and the Prairie CARE (Conservation of Agriculture, Resources and **Environment**) program. The wetlands conservation and other habitat projects addressed in these and similar programs, not only benefit game **species**, but other **endangered species** of plants and animals as well. NAWMP (an agreement between the United States and Canada) alone protects over 5.5 million acres (2.2 million ha) of waterfowl habitat. In 2002, the North American Wetlands Conservation Act (NAWCA) granted the DU one million dollars to be put towards a new wetlands in Ohio.

On balance, DU has had a major, positive impact on North American waterfowl habitat and management. Millions of acres of wetlands have been protected, enhanced, and managed in Canada, the United States, and Mexico. However, the continued decline in waterfowl populations may require the organization to redirect some of its efforts to population management and preservation issues.

Ducktown, Tennessee

Tucked in a valley of the Cherokee **National Forest**, on the border of Tennessee, North Carolina, and Georgia, Ducktown once reflected the beauty of the surrounding Appalachian Mountains. Instead, Ducktown and the valley known as the **Copper** Basin now form the only **desert** east of the Mississippi. Mined for its rich copper lode since the 1850s, it had become a vast stretch of lifeless, red-clay hills. It was an early and stark lesson in the devastation that **acid rain** and **soil erosion** can wreak on a landscape, one of the few man-made landmarks visible to the astronauts who landed on the moon.

Prospectors came to the basin during a gold rush in 1843, but the closest thing to gold they discovered was copper, and most went home. But by 1850, entrepreneurs realized the value of the ore, and a new rush began to mine the area. Within five years, 30 companies had dug beneath the **topsoil** and made the basin the country's leading producer of copper.

The only way to separate copper from the zinc, iron, and sulfur present in Copper Basin rock was to roast the ore at extremely high temperatures. Mining companies built giant open pits in the ground for this purpose, some as wide as 600 ft (183 m) and as deep as a 10-story building. Fuel for these fires came from the surrounding forests. The forests must have seemed a limitless resource, but it was not long before every tree, branch, and stump for 50 mi^2 (130 km^2) had been torn up and burned. The fires in the pits emitted great billows of **sulfur dioxide** gas—so thick people could get lost in the clouds even at high noon—and this gas mixed with water and oxygen in the air to form sulfuric **acid**, which is main component in acid rain. Saturated by acidic moisture and choked by the remaining sulfur dioxide gas and dust, the undergrowth died and the soil became poisonous to new plants. **Wildlife** fled the shelterless hillsides. Without root systems, virtually all the soil washed into the Ocoee River, smothering aquatic life. Open-range grazing of cattle, allowed in Tennessee until 1946, denuded the land of what little greenery remained.

Soon after the turn of the century, Georgia filed suit to stop the **air pollution** which was drifting out of this corner of Tennessee. In 1907, the Supreme Court, in a decision written by Justice Oliver Wendell Holmes, ruled in Georgia's favor, and the sulfur clouds ceased in the Copper Basin. It was one of the first environmental-rights decisions in the United States. That same year, the Tennessee Copper Company designed a way to capture the sulfur fumes, and sulfuric acid, rather than copper, became the area's main product. It remains so today.

Ducktown was the first mining settlement in the area, and residents now take a curious pride not only in the town's history, but in the eerie moonscape of red hills and painted cliffs that surrounds it. Since the 1930s, Tennessee Copper Company, the **Tennessee Valley Authority**, and the **Soil Conservation Service** have worked to restore the land, planting hundreds of loblolly pine and black locust trees. Their efforts have met with little success, but new reforestation techniques such as slow-release **fertilizer** have helped many new plantings survive. Scientists hope to use the techniques practiced here on other deforested areas of the world. Ironically, many of the townspeople want to preserve a piece of the scar, both for its unique beauty and the environmental lesson of what human enterprise can do to **nature**, as well as what it can undo. *See also* Acid waste; Ashio, Japan; Mine spoil waste; Smelter; Sudbury, Ontario; Surface mining; Trail Smelter arbitration

Dunes and dune erosion

Dunes are small hills, mounds or ridges of wind-blown **soil** material, usually sand, that are formed in both coastal and inland areas. The formation of coastal or inland dunes requires a source of loose sandy material and dry periods during which the sand can be picked up and transported by the wind. Dunes exist independently of any fixed surface feature and can move or drift from one location to another over time. They are the result of natural **erosion** processes and are natural features of the landscape in many coastal areas and deserts, yet they also can be symptoms of land degradation. Inland dunes are either an expression of aridity or can be

indicators of desertification—the result of long-term land degradation in dryland areas.

Coastal dunes are the result of marine erosion in which sand is deposited on the shore by wave action. During low tide, the beach sand dries and is dislodged and transported by the wind, usually over relatively short distances. Depending on the local **topography** and direction of the prevailing winds, a variety of shapes and forms can develop—from sand ridges to parabolic mounds. The upper few centimeters of coastal dunes generally contain chlorides from salt spray and wind-blown salt. As a result, attempts to stabilize coastal dunes with vegetation are often limited to salt-tolerant plants.

The occurrence of beaches and dunes together have important implications for coastal areas. A beach absorbs the energy of waves and acts as a **buffer** between the sea and the dunes behind it. Low lying coastlines are best defended against high tides by consolidated sand dunes. In such cases, maintaining a wide, high beach that is backed by stable dunes is desirable.

Engineering structures along coastal areas and the mouths of rivers can affect the formation and erosion of beaches and coastal dunes. In some instances it is desirable to build and widen beaches to protect coastal areas. This can require the construction of structures that trap littoral drift, rock mounds to check wave action, and sea walls that protect areas behind the beach from heavy wave action. Where serious erosion has occurred, artificial replacement of beach sands may be necessary. Such methods are expensive and require considerable engineering effort and the use of heavy equipment.

The **weathering** of rocks, mainly sandstone, is the origin of material for *inland dunes*. However, whether or not sand dunes form, depends on the vegetative cover condition and use of the land. In contrast to coastal dunes, that are often considered to be beneficial to coastal areas, inland dunes can be indicators of land degradation where the protective cover of vegetation has been removed as a result of inappropriate cultivation, **overgrazing**, construction activities, and so forth. When vegetative cover is absent, soil is highly susceptible to both water and wind erosion. The two work together in drylands to create sources of soil that can be picked up and transported either downwind or downstream. The flow of water moves and exposes sand grains and supplies fresh material that results in deposits of sand in flood plains and ephemeral **drainage** systems. Before dunes can develop in such areas, there must be long dry periods between periodic or episodic sediment-laden flows of water. Wind erosion occurs where such sand deposits from water erosion are exposed to the energy of wind, or in areas that are devoid of vegetative cover.

Where sand is the principle size soil particle and where high wind velocities are common, sand particles are moved by a process called saltation and creep. Sand dunes form under such conditions and are shaped by wind patterns over the landscape. Complex patterns can be formed—the result of interactions of wind, sand, the ground surface topography, and any vegetation or other physical barriers that exist. These patterns can be sword like ridges, called longitudinal dunes, crescentic accumulations or barchans, turret-shaped mounds, shallow sheets of sand, or large seas of transverse dunes. The typical pattern is one of a gradual long slope on the windward side of the dune, dropping off sharply on the leeward side.

Exposed sand dunes can move up to 11 yd (10 m) annually in the direction of the prevailing wind. Such dunes encroach upon areas, covering farmlands, pasture lands, **irrigation** canals, urban areas, railroads and highways. Blowing sand can mechanically injure and kill vegetation in its path and can eventually bury croplands or **rangelands**. If left unchecked, the drifting sand will expand and lead to serious economic and environmental losses.

Worldwide, dryland areas are those most susceptible to wind erosion. For example, 22% of Africa north of the Equator is severely affected by wind erosion as is over 35% of the land area in the Near East. As a result, inland dunes represent a significant landscape component in many **desert** regions. For example, dunes represent 28%, 26%, and 38% of the landscape of the Saharan Desert, Arabian Desert, and **Australia**, respectively (Heathcote 1983). In 1980, Walls estimated that 1.3 billion hectares of land were covered by sand dunes globally. Although dunes can be symptoms of **land use** problems, in some areas they are part of a natural dryland landscape that are considered to be features of beauty and interest. Sand dune have become popular recreational areas in parts of the United States, including the Great Sand Dune National Monument in southern Colorado with its 229-yd (210-m) high dunes that cover a 158-mi^2 (254.4-km^2) area, and the Indiana Dunes State Park along the shore of Lake Michigan.

When dune formation and encroachment represent significant environmental and economic problems, sand dune stabilization and control should be undertaken. Dune stabilization may initially require one or more of the following: applications of water, oil, bitumens emulsions, or chemical stabilizers to improve the cohesiveness of surface sands; the reshaping of the landscape such as construction of foredunes that are upwind of the dunes, and armoring of the surface using techniques such as hydroseeding, jute mats, mulching and asphalt; and constructing fences to reduce wind velocity near the ground surface. Although sand dune stabilization is the necessary first step in controlling this process, the establishment of a vegetative cover is a necessary

The dunes of Nags Head, North Carolina. (Photograph by Jack Dermid, National Audubon Society Collection. Photo Researchers Inc. Reproduced by permission.)

condition to achieve long-term control of sand dune formation and erosion. Furthermore, stabilization and revegetation must be followed with appropriate land management that deals with the causes of dune formation in the first place. Where dune erosion has not progressed to a seriously degraded state, dunes can become reclaimed through natural regeneration simply by protecting the area against livestock grazing, all-terrain vehicles, and foot traffic.

Vegetation stabilizes dunes by decreasing wind speed near the ground and by increasing the cohesiveness of sandy material by the addition of organic colloids and the binding action of roots. Plants trap the finer wind-blown soil particles, which helps improve **soil texture**, and they also improve the **microclimate** of the site, reducing soil surface temperatures. Upwind barriers or windbreak plantings of vegetation, often trees or other woody perennials, can be effective in improving the success of revegetating sand dunes. They reduce wind velocities, help prevent exposure of plant roots from the drifting sand, and protect plantings from the abrasive action of blowing sand. Areas that are susceptible to sand dune encroachment can likewise be protected by using fences or windbreak plantings that reduce wind velocities near the ground surface. Because of the severity of sand dune environments, it can be difficult to find plant **species** that can be established and survive. In addition, any plantings must be protected against exploitation, for example, from grazing or fuelwood harvesting.

The expansion of sand dunes resulting from **desertification** not only represent environmental problems, but they also represent serious losses of productive land and a financial hardship for farmers and others who depend upon the land for their livelihood. Such problems are particularly acute in many of the poorer dryland countries of the world and deserve the attention of governments, international agencies, and nongovernmental organizations who need to direct their efforts toward the causes of soil erosion and dune formation.

Dust Bowl

"Dust Bowl" is a term coined by a reporter for the *Washington* (D.C.) *Evening Star* to describe the effects of severe wind **erosion** in the Great Plains during the 1930s, caused by severe **drought** and lack of **conservation** practices.

For a time after World War I, agriculture prospered in the Great Plains. Land was rather indiscriminantly plowed and planted with cereals and row crops. In the 1930s, the total cultivated land in the United States increased, reaching 530 million acres (215 million ha), its highest level ever. Cereal crops, especially wheat, were most prevalent in the Great Plains. Summer fallow (cultivating the land, but only planting every other season) was practiced on much of the land. Moisture, stored in the **soil** during the fallow (uncropped) period, was used by the crop the following year. In a process called dust **mulch**, the soil was frequently clean tilled to leave no crop residues on the surface, control weeds, and, it was thought at the time, preserve moisture from evaporation. Frequent cultivation and lack of crop canopy and residues optimized conditions for wind erosion during the droughts and high winds of the 1930s.

During the process of wind erosion, the finer particles (**silt** and clay) are removed from the **topsoil**, leaving coarser-textured sandy soil. The fine particles carry with them higher concentrations of organic matter and plant nutrients, leaving the remaining soil impoverished and with a lower water storage capacity. Wind erosion of the Dust Bowl reduced the productivity of affected lands, often to the point that they could not be farmed economically.

While damage was particularly severe in Texas, Oklahoma, Colorado, and Kansas, erosion occurred in all of the Great Plains states, from Texas to North Dakota and Montana, even into the Canadian **Prairie** Provinces. The eroding soil not only prevented the growth of plants, it uprooted established ones. **Sediment** filled fence rows, stream channels, road ditches, and farmsteads. Dirt coated

the insides of buildings. Airborne dust made travel difficult because of decreased **visibility**; it also impaired breathing and caused **respiratory diseases**.

Dust from the Great Plains was carried high in the air and transported as far east as the Atlantic seaboard. In places, 3–4 in (7–10 cm) of topsoil was blown away, forming **dunes** 15–20 ft (4.6–6.1 m) high where the dust finally came to rest. In a 20-county area covering parts of southwestern Kansas, the Oklahoma strip, the Texas Panhandle, and southeastern Colorado, a soil-erosion survey by the **Soil Conservation Service** showed that 80% of the land was affected by wind erosion, 40% of it to a serious degree.

The droughts and resultant wind erosion of the 1930s created widespread economic and social problems. Large numbers of people migrated out of the Dust Bowl area during the 1930s. The **migration** resulted in the disappearance of many small towns and community services such as churches, schools, and local units of government.

Following the disaster of the Dust Bowl, the 1940s saw dramatically improved economic and social conditions with increased precipitation and improved crop prices. Gradually, changes in farming practices have also taken place. Much of the severely damaged and marginal land has been returned to grass for livestock grazing. Non-detrimental tillage and management practices, such as **conservation tillage** (stubble mulch, mulch, and residue tillage); use of tree, shrub, and grass windbreaks; maintenance of crop residues on the soil surface; and better machinery have all contributed to improved soil conditions. Annual cropping or a three-year rotation of wheat-sorghum-fallow has replaced the alternate crop-fallow practice in many areas, particularly in the more humid areas of the West.

While the extreme conditions of drought and land mismanagement of the Dust Bowl years have not been repeated since the 1930s, wind erosion is still a serious problem in much of the Great Plains. According to the **Soil Conservation** Service, the states with the most serious erosion per unit area in 1982 were Texas, Colorado, Nevada, and Montana. *See also* Arable land; Desertification; Overgrazing; Soil eluviation; Tilth; Water resources

E

Earth Charter

It is the objective of the Earth Charter to set forth an inspiring vision of the fundamental principles of a global partnership for **sustainable development** and environmental **conservation**. The Earth Charter initiative reflects the conviction that a radical change in humanity's attitudes and values is essential to achieve social, economic, and ecological well-being in the twenty-first century. The Earth Charter project is part of an international movement to clarify humanity's shared values and to develop a new global ethics, ensuring effective human cooperation in an interdependent world.

There were repeated efforts to draft the Earth Charter beginning in 1987. Early in 1997 an Earth Charter Commission was formed by the Earth Council and **Green Cross** International. The Commission prepared an Earth Charter which it was circulated as a people's treaty beginning in 1998. The Charter was then submitted to the United Nations General Assembly in the year 2000. On June 29, 2000, the official Earth Charter was established at the Peace Palace in The Hague, Holland.

Historical background, 1945–1992

The role and significance of the Earth Charter are best understood in the context of the United Nations' ongoing efforts to identify the fundamental principles essential to world security. When the U.N. was established in 1945, its agenda for world security emphasized peace, human rights, and equitable socioeconomic development. No mention was made of the **environment** as a common concern, and little attention was given to ecological well-being in the U.N.'s early years. However, since the Stockholm Conference on the Human Environment in 1972, ecological security has emerged as a fourth major concern of the United Nations.

Starting with the Stockholm Declaration, the world's nations have adopted a number of declarations, charters, and treaties that seek to create a global alliance that effectively integrates and balances development and conservation. In addition, a variety of nongovernmental organizations have drafted and circulated their own declarations and people's treaties. These documents reflect a growing awareness that humanity's social, economic, and environmental problems are interconnected and require integrated solutions. The Earth Charter initiative builds on these efforts.

The World Charter for Nature, which was adopted by the U.N. General Assembly in 1982, was a progressive declaration of ecological and ethical principles for its time. It remains a stronger document than any that have followed from the point of view of **environmental ethics**. However, in its 1987 report, ***Our Common Future***, the U.N. World Commission on Environment and Development (WCED) issued a call for "a new charter" that would "consolidate and extend relevant legal principles," creating "new norms...needed to maintain livelihoods and life on our shared planet" and "to guide state behavior in the transition to sustainable development." The WCED also recommended that the new charter "be subsequently expanded into a Convention, setting out the sovereign rights and reciprocal responsibilities of all states on environmental protection and sustainable development."

The WCED recommendations, together with deepening environmental and ethical concerns, spurred efforts in the late 1980s to create an Earth Charter. However, before any U.N. action was initiated on the Earth Charter, the Commission on **Environmental Law** of the World Conservation Union (IUCN) drafted the convention proposed in *Our Common Future*. The IUCN Draft International Covenant on Environment and Development presents an integrated legal framework for existing and future international and national environmental and sustainable development law and policy. Even though the IUCN Draft Covenant was presented at the United Nations in 1995 official negotiations have not yet begun on this treaty which many environmentalists believe is urgently needed to clarify, synthesize, and further develop international sustainable development law.

The United Nations Conference on Environment and Development (UNCED), or Earth Summit held in Rio de

Janeiro, Brazil, in 1992 did take up the challenge of drafting the Earth Charter. A number of governments prepared recommendations. Many nongovernmental organizations, including groups representing the major faiths, became actively involved. While the resulting Rio Declaration on Environment and Development is a valuable document, it falls short of the aspirations that many groups have had for the Earth Charter.

The Earth Charter Project, 1994–2000

A new Earth Charter initiative began in 1994 under the leadership of Maurice Strong, the former secretary general of UNCED and chairman of the newly formed Earth Council, and Mikhail Gorbachev, acting in his capacity as chairman of Green Cross International. The Earth Council was created to complete the unfinished business of UNCED and to promote implementation of Agenda 21, the Earth Summit's action plan. Jim MacNeill, former secretary general of the WCED and Prime Minister Ruud Lubbers of The Netherlands were instrumental in facilitating the organization of the new Earth Charter project. Ambassador Mohamed Sahnoun of Algeria served as the executive director of the project during its initial phase, and its first international workshop was held at the Peace Palace in The Hague in May 1995. Representatives from 30 countries and more than 70 different organizations participated in the workshop. Following this event, the secretariat for the Earth Charter project was established at the Earth Council in San José, Costa Rica.

A worldwide Earth Charter consultation process was organized by the Earth Council in connection with the Rio+5 review in 1996 and 1997. The Rio+5 review, which culminated with a special session of the United Nations General Assembly in June 1997, sought to assess progress toward sustainable development since the Rio Earth Summit and to develop new partnerships and plans for implementation of Agenda 21. The Earth Charter consultation process engaged men and women from all sectors of society and all cultures in contributing to the Earth Charter's development. A special program was created to contact and involve the world's religions, interfaith organizations, and leading religious and ethical thinkers. A special indigenous people's network was also organized by the Earth Council.

Early in 1997, an Earth Charter Commission was formed to oversee the project. The 23 members represent the major regions of the world and different sectors of society. The Commission issued a Benchmark Draft Earth Charter in March 1997 at the conclusion of the Rio+5 Forum in Rio de Janeiro. The Forum was organized by the Earth Council as part of its independent Rio+5 review, and it brought together more than 500 representatives from civil society and national councils of sustainable development. The Benchmark Draft reflected the many and diverse contributions received through the consultation process and from the Rio+5 Forum. The Commission extended the Earth Charter consultation until early 1998, and the Benchmark Draft was circulated widely as a document in progress.

The Earth Charter concept

A consensus developed that the Earth Charter should be: a statement of fundamental principles of enduring significance that are widely shared by people of all races, cultures, and religions; a relatively brief and concise document composed in a language that is inspiring, clear, and meaningful in all tongues; the articulation of a spiritual vision that reflects universal spiritual values, including but not limited to ethical values; a call to action that adds significant new dimensions of value to what has been expressed in earlier relevant documents; a people's charter that serves as a universal code of conduct for ordinary citizens, educators, business executives, scientists, religious leaders, nongovernmental organizations, and national councils of sustainable development; and a declaration of principles that can serve as a "soft law" document when adopted by the U.N. General Assembly. The Earth Charter was designed to focus on fundamental principles with the understanding that the IUCN Covenant and other treaties will set forth the more specific practical implications of these principles.

The Earth Charter draws upon a variety of resources, including **ecology** and other contemporary sciences, the world's religious and philosophical traditions, the growing literature on global ethics and the ethics of environment and development, the practical experience of people living sustainably, as well as relevant intergovernmental and nongovernmental declarations and treaties. At the heart of the new global ethics and the Earth Charter is an expanded sense of community and moral responsibility that embraces all people, **future generations**, and the larger community of life on Earth. Among the values affirmed by the Benchmark Draft are: respect for Earth and all life; protection and restoration of the health of Earth's ecosystems; respect for human rights, including the right to an environment adequate for human well-being; eradication of poverty; nonviolent problem solving and peace; the equitable sharing of resources; democratic participation in decision making; accountability and transparency in administration; universal education for sustainable living; and a sense of shared responsibility for the well-being of the Earth community.

[*Steven C. Rockefeller*]

Earth Day

The first Earth Day, April 22, 1970, attracted over 20 million participants in the United States. It launched the modern environmental movement and spurred the passage of several important environmental laws. It was the largest demonstration in history. People from all walks of life took part in marches, teach-ins, rallies, and speeches across the country. Congress adjourned so that politicians could attend hometown events, and cars were banned from New York's Fifth Avenue.

The event had a major impact on the nation. Following Earth Day, **conservation** organizations saw their memberships double and triple. Within months, the **Environmental Protection Agency** (EPA) was created; Congress also revised the **Clean Air Act**, the **Clean Water Act**, and other environmental laws.

The concept for Earth Day began with Senator Gaylord Nelson, a Wisconsin Democrat, who in 1969 proposed a series of environmental teach-ins on college campuses across the nation. Hoping to satisfy a course requirement at Harvard by organizing a teach-in there, law student Denis Hayes flew to Washington, DC, to interview Nelson. The senator persuaded Hayes to drop out of Harvard and organize the nationwide series of events that were only a few months away. According to Hayes, Wednesday, April 22 was chosen because it was a weekday and would not compete with weekend activities. It also came before students would start "cramming" for finals, but after the winter thaw in the North.

Twenty years later, Earth Day anniversary celebrations attracted even greater participation. An estimated 200 million people in over 140 nations were involved in events ranging from a concert and rally of over a million people in New York's Central Park, to a festival in Los Angeles that attracted 30,000, to a rally of 350,000 at the National Mall in Washington, D.C.

Earth Day 1990 activities included planting trees; cleaning up roads, highways, and beaches; building bird houses; **ecology** teach-ins; and **recycling** cans and bottles. A convoy of **garbage** trucks drove through the streets of Portland, Oregon, to dramatize the lack of **landfill** space. Elsewhere, children wore gas masks to protest **air pollution**, others marched in parades wearing costumes made from recycled materials, and some even released ladybugs into the air to demonstrate alternatives to harmful pesticides. The gas-guzzling car that was buried in San Jose, California, during the first Earth Day was dug up and recycled.

Abroad, Berliners planted 10,000 trees along the East-West border. In Myanmar, there were protests against the killing of **elephants**. Brazilians demonstrated against the destruction of their tropical rain forests. In Japan, there were demonstrations against disposable chopsticks, and 10,000 people attended a concert on an island built on reclaimed land in Tokyo Bay.

The 1990 version was also organized by Denis Hayes, with help from hundreds of volunteers. This time, the event was well organized and funded; it was widely-supported by both environmentalists and the business community. The United Auto Workers Union sent Earth Day booklets to all of its members, the National Education Association sent information to almost every teacher in the country, and the Methodist Church mailed Earth Day sermons to over 30,000 ministers.

The sophisticated advertising and public relations campaign, licensing of its logo, and sale of souvenirs provoked criticism that, Earth Day had become too commercial. Even oil, chemical, and nuclear firms joined in and proclaimed their love for **nature**. But Hayes defended the professional approach as necessary to maximize interest and participation in the event, to broaden its appeal, and to launch a decade of environmental activism that would force world leaders to address the many threats to the planet. He also pointed out that while foundations, corporations, and individuals had donated $3.5 million, organizers turned down over $4 million from companies that were thought to be harming the **environment**.

The 30-year anniversary of the event was also organized by Hayes. Unfortunately, it did not produce the large numbers of the prior anniversary celebration. The movement had reached over 5,000 environmental groups who helped organize local rallies, and hundreds of thousands of people met in Washington to hear political, environmental, and celebrity speakers.

Hayes believes that the long-term success of Earth Day in securing a safe future for the planet depends on getting as many people as possible involved in **environmentalism**. The Earth Day celebrations he helped organize a have been a major step in that direction.

Earth First!

Earth First! is a radical and often controversial environmental group founded in 1979 in response to what **Dave Foreman** and other founders believed to be the increasing co-optation of the environmental movement. For Earth First! members, too much of the environmental movement has become lethargic, compromising, and corporate in its orientation. To avoid a similar fate, Earth First! members have restricted their use of traditional fund-raising techniques and have sought a non-hierarchical organization with neither a professional staff nor formal leadership.

A movement established by and for self-acknowledged environmental hardliners, Earth First!'s general stance is reflected in its slogan, "No compromise in the defense of Mother Earth." Its policy positions are based upon principles of **deep ecology** and in particular on the group's belief in the **intrinsic value** of all natural things. Its goals include preserving all remaining **wilderness**, ending **environmental degradation** of all kinds, eliminating major **dams**, establishing large-scale ecological preserves, slowing and eventually reversing human **population growth**, and reducing excessive and environmentally harmful consumption.

Combining biocentrism with a strong commitment to activism, Earth First! does not restrict itself to lobbying, lawsuits, and letter-writing, but also employs direct action, civil disobedience, "guerrilla theater," and other confrontational tactics, and in fact is probably best known for its various clashes with the **logging** industry, particularly in the Pacific Northwest. Earth First! members and sympathizers have been associated with controversial tactics including the chopping down of billboards and **monkey-wrenching**, which includes pouring sand in bulldozer gas tanks, spiking trees, sabotaging drilling equipment, and so forth. Officially, the organization purports neither to condone nor condemn such tactics.

Earth First! encourages people to respect **species** and wilderness, to refrain from having children, to recycle, to live simpler, less destructive lives, and to engage in civil disobedience to thwart environmental destruction. During the summer of 1990, the group sponsored its most noted event, "Redwood Summer." Activists from around the United States gathered in the Northwest to protest large-scale logging operations, to call attention to environmental concerns, to educate and establish dialogues with loggers and the local public, and to engage in civil disobedience.

Earth First! also sponsors a **Biodiversity** Project for protecting and restoring natural ecosystems. Its Ranching Task Force educates the public about the consequences of **overgrazing** in the American West. The **Grizzly Bear** Task Force focuses on the preservation of the grizzly bear in the Rockies and the reintroduction of the species to its historical range throughout North America. Earth First!'s wider Predator Project seeks the restoration of all native predators to their respective habitats and ecological roles. Carmageddon is an anti-car campaign Earth First! sponsors in the United Kingdom. Other Earth First! projects seek to defend **redwoods** and other native forests, encourage direct action against the fur industry, intervene in government-sponsored wolf-control programs in the U.S. and Canada, and protest government and business decisions which have environmentally destructive consequences for tropical rain forests.

[*Lawrence J. Biskowski*]

Earth Island Institute

The Earth Island Institute (EII) was founded by David Brower in 1982 as a nonprofit organization dedicated to developing innovative projects for the **conservation**, preservation, and restoration of the global **environment**. In its earliest years, the Institute worked primarily with a volunteer staff and concentrated on projects like the first Conference on the Fate of the Earth, publication of *Earth Island Journal*, and the production of films about the plight of **indigenous peoples**. In 1985 and again in 1987, EII expanded its facilities and scope, opening office space and providing support for a number of allied groups and projects. Its membership now numbers approximately 35,000.

EII conducts research on, and develops critical analyses of, a number of contemporary issues. With sponsored projects ranging from saving **sea turtles** to encouraging land restoration in Central America, EII does not restrict its scope to traditionally "environmental" goals but rather pursues what it sees as ecologically-related concerns such as human rights, economic development of the **Third World**, economic conversion from military to peaceful production, and inner city poverty, among others. But much of its mission is to be an environmental educator and facilitator. In that role EII sponsors or participates in numerous programs designed to provide information, exchange viewpoints and strategies, and coordinate efforts of various groups. EII even produces music videos as part of its **environmental education** efforts.

EII is perhaps best known for its efforts to halt the use of drift nets by tuna boats, a practice which is often fatal to large numbers of **dolphins**. After an EII biologist signed on as a crew member aboard a Latin American tuna boat and managed to document the slaughter of dolphins in drift nets, EII brought a lawsuit to compel more rigorous enforcement of existing laws banning tuna caught on boats using such nets. EII also joined with other environmental groups in urging a consumer boycott of canned tuna. These efforts were successful in persuading the three largest tuna canners to pledge not to purchase tuna caught in drift nets. The monitoring of tuna fishing practices is an ongoing EII project.

EII also sponsors a wide variety of other projects. Its Energy Program promotes energy efficient technology. Its Friends of the Ancient Forest program aims at the protection of old-growth forests on the Pacific Coast. Baikal Watch works for the permanent protection of biologically unique **Lake Baikal**, Russia. The Climate Protection Institute publishes the *Greenhouse Gas-ette* and develops public education material about changes in global climate. EII participates in the International Green Circle, an ecological restoration program which matches volunteers with ongoing projects worldwide. EII's Sea Turtle Restoration Project investigates threats to the world's endangered sea turtles, organizes and educates United States citizens to protect the turtles, and works with Central American sea turtle restoration projects. The **Rain Forest** Health Alliance develops educational materials and programs about the biological diversity of tropical rain forests. The Urban **Habitat** Program develops multicultural environmental leadership and organizes efforts to restore urban neighborhoods.

EII administers a number of funds designed to support creative approaches to environmental conservation, preservation, and restoration to support activists exploring the use of citizen suit provisions of various statutes to enforce environmental laws and to help develop a Green political movement in the United States. EII also sponsors several international conferences, exchange programs, and publication projects in support of various environmental causes.

Earth Liberation Front

Earth Liberation Front (ELF) is a grassroots environmental group that the Federal Bureau of Investigation labeled "a serious terrorism threat." Since 1996, ELF and the Animal Liberation Front (ALF) committed more than 600 acts of vandalism that resulted in more than $43 million in damage, an FBI terrorism expert reported to Congress in 2002.

James Jarboe, the FBI section chief for Domestic Terrorism, told Congress that it was hard to track down ELF and AlF members because the two groups have little organized structure. According to the ELF link on the ALF Web site, there is no designated leadership nor formal membership. ELF and ALF claim responsibility for their activities by e-mail, fax, and other communications usually sent to the media.

In 2002, media information was provided by the North American Earth Liberation Front Press Office. Spokesman Leslie James Pickering wrote that he received anonymous communiqués from ELF and further distributed them.

ELF describes itself as an international underground organization dedicated "to stop the continued destruction of the natural environment." Members join anonymous cells that may consist of one person or more. Members of one cell do not know the identity of members in other cells, a structure that prevents activists in one cell from being compromised should members in another cell become disaffected. People act on their own and carry out actions following anonymous ELF postings. ELF actions include sabotage and property damage.

ELF postings include guidelines for taking action. One guideline is to inflict "economic damage on people who profit from the destruction and exploitation of the natural environment." Another guideline is to reveal and educate the public about the "atrocities" committed against the **environment**. The third guideline is to take all needed precautions against harming any animal, human and non-human.

ELF is an outgrowth of **Earth First!**, a group formed during the 1980s to promote environmental causes. Earth First! held protests and civil disobedience events, according to the FBI. In 1984, Earth First! members began a campaign of "tree spiking." to prevent loggers from cutting down trees. Members inserted metal or ceramic spikes into trees. The spikes damaged saws when loggers tried to cut down trees.

When Earth First! members in Brighton, England disagreed with proposals to make their group more mainstream, radical members of the group founded the Earth Liberation Front in 1992. The following year, ELF aligned itself with ALF.

The Animal Liberation Front was started in Great Britain during the mid-1970s. The loosely organized movement had the goal of ending animal abuse and exploitation of animals. An American ALF branch was started in the late 1970s. According to the FBI, people became members by participating in "direct action" activities against companies or people using animals for research or economic gain. ALF activists targeted animal research laboratories, fur companies, mink farms, and restaurants.

ELF and ALF declared mutual solidarity in a 1993 announcement. The following year, the San Francisco branch of Earth First! recommended that the group mainstream itself away from ELF and its unlawful activities. ELF calls its activities "monkeywrenching.", a term that refers to actions such as tree spiking, arson, sabotage of **logging** equipment, and property destruction.

In a 43-page document titled "Year End Report for 2001," ELF and ALF claimed responsibility for 67 illegal acts that year. ELF claimed sole credit for setting a fire that year that caused $5.4 million in damage to a University of Washington horticulture building. The group also took sole credit for a 1998 fire set at a Vail, Colorado ski resort. Damage totaled $12 million for the arson that destroyed four ski lifts, a restaurant, a picnic facility, and a utility building, according to the FBI.

ELF issued a statement after the arson saying that the fire was set to protect the lynx, which was being reintroduced to the Rocky Mountains. "Vail, Inc. is already the largest ski operation in North American and now wants to expand even further...This action is just a warning. We will be back if this greedy corporation continues to trespass into wild and unroaded areas," the statement said.

In 2002, ELF claimed credit for a fire that caused $800,000 in damage at the University of Minnesota Microbial Plant and Genomics Center. ELF targeted the genetic crop laboratory because of its efforts to "control and exploit" **nature**.

"Eco-terrorism" is the term used by the FBI to define illegal activities related to **ecology** and the environment. These activities involve the "use of criminal violence against innocent victims or property by an environmentally-oriented group."

Although ELF members are difficult to track, several arrests have been made. In February 2001, two teen-age boys pleaded guilty to setting fires at a home construction site in Long Island, New York. In December of that year, a man was also charged with spiking 150 trees in Indiana state forests. In his Congress testimony, Jarboe said that cooperation among law enforcement agencies was essential to respond efficiently to eco-terrorism. As of 2002, the FBI has joint terrorism task forces in 44 cities and the bureau plans to have task forces in all 56 of its field offices by the end of 2003.

Earth Pledge Foundation

Created in 1991 by attorney Theodore W. Kheel, the Earth Pledge Foundation (EPF) is concerned with the impact of technology on society. Recognizing the often delicate balance between economic growth and environmental protection, EPF encourages the implementation of sustainable practices, especially in community development, tourism, cuisine, and architecture.

As a result of the **United Nations Earth Summit** (Rio de Janeiro) the UN pledged its commitment to the principles of sustainable development—to foster "development meeting the needs of the present without compromising the ability of **future generations** to meet their own needs."

Created for the Summit in support of the principles, the Earth Pledge was prominently displayed throughout the event. Heads of state, ambassadors, delegates, and prominent dignitaries from around the world stood in line to sign their names on a large Earth Pledge board. Since the Summit, millions have taken the Earth Pledge: "Recognizing that people's actions towards **nature** and each other are the source of growing damage to the **environment** and to resources needed to meet human needs and ensure survival, I pledge to act to the best of my ability to help make the Earth a secure and hospitable home for present and future generations."

In early 1996, Earth Pledge created the Business Coalition for Sustainable Cities (BCSC) to influence the development of cities as centers of commerce, employment, **recreation**, and settlement. Chaired by William L. Lurie, former president of The Business Roundtable, the BCSC provides business leaders a forum to address issues of major importance to our cities in ways that ensure economic viability while at the same time promoting respect for the environment. One event sponsored by the BCSC was a seven-course dinner prepared by 12 of the nation's most environmentally-conscious chefs to showing off that restaurants, one of the largest industries and employers, can practice the principles of sustainable cuisine. The BCSC hosted the event with the theme that good food can be well-prepared without adversely impacting health, culture or environment. This theme was elaborated on in 2000 when the Sustainable Cuisine Project was established to develop and teach cooking classes.

The latest development by Earth Pledge is the creation of the web site <farmtotable.org>. This web site highlights local farmers of the New York region and give consumers a direct link to fresh food news.

Earth Pledge has also formed a number of alliances to further their goals with groups such as: The Foundation for Prevention and Resolution of Conflict (PERC—founded by Theodore Kheel); the United Nations Environmental Programme (UNEP); EarthKind International; the New England Aquarium.

As a joint project with the New England Aquarium, EPF sponsors a marine awareness project that educates people on the importance of coastlines and aquatic resources to the **sustainable development** of the world's cities. The project emphasizes that many countries have water shortages due to inefficient use of their water supply, degradation of their water by **pollution** and unsustainable usage of **groundwater** resources.

In late 1995, Earth Pledge co-sponsored the first Caribbean Conference on Sustainable Tourism with the UN Department for Policy Coordination and Sustainable Development, EarthKind International and UNEP. The Conference brought together officials from government and business to discuss strategies for developing a healthy tourist economy, sound infrastructure, environmental protection, and community participation.

The foundation has constructed an environmentally-sensitive building, Foundation House, to display their solutions for improving **air quality** and **energy efficiency**. Sustainable features include heating, cooling, and lighting systems that minimize consumption of **fossil fuels**; increased ventilation and use of natural daylight; an auditorium for conferences with Internet access and computer lab for training. The Foundation House houses exhibits, including one on enhancing efficiency of the workplace for the benefit of the staff.

Earth Pledge continues to develop smaller organizations and promote companies that participate in sustainable practices.

Earthquake

Earthquakes have been around for as long as the planet and have plagued humans throughout history. With no warning, major earthquakes strike populated areas of the world every year, killing hundreds, injuring thousands, and causing hundreds of millions of dollars in damage. Yet despite millions of dollars and decades of research, seismologists (scientists who study earthquakes) are still unable to predict precisely when and where an earthquake will happen.

An earthquake is a geological event in which rock masses below the surface of the earth suddenly shift, releasing energy and sending out strong vibrations to the surface. Most earthquakes are caused by movement along a fault line, which is a fracture in the earth's crust. Thousands of earthquakes happen each day around the world, but most are too small to be felt.

Earth is covered by a crust of rock that is broken into numerous plates. The plates float on a layer of molten (liquid) rock within the earth called the mantel. This molten rock moves and flows, and this movement is thought to cause the shifting of the plates. When plates move, they either slide past, bump into, overrun, or pull away from each other. The movement of plates is called **plate tectonics**. Boundaries between plates are called faults.

Earthquakes can occur when there are any of the four types of movement along a fault. Earthquakes along the San Andreas and Hayward faults in California occur because of two plates sliding past one another. Earthquakes also occur if one plate overruns another. When this happens one plate is pushed under the other plate, as on the western coast of South America, the northwest coast of North America, and in Japan. If plates collide but neither is pushed downwards, as they do crossing Europe and Asia from Spain to Vietnam, earthquakes result as the plates are pushed into each other and are forced upwards, creating high mountain ranges. Many faults at the floor of the ocean are between two plates moving apart. Many earthquakes with centers at the floor of the ocean are caused by this kind of movement.

The relative size of earthquakes is measured by the Richter Scale, which measures the energy an earthquake releases. Each whole number increase in value on the Richter scale indicates a ten-fold increase in the energy released and a thirty–fold increase in ground motion. An earthquake measuring 8 on the Richter scale is ten times more powerful, therefore, than an earthquake with a Richter magnitude of 7. Another scale, called the Mercalli Scale uses observations of damage (such as fallen chimneys) or people's assessments of effects (such as mild or severe ground shaking) to describe the intensity of a quake. The Richter Scale is open-ended, while the Mercalli scale ranges from 1–12.

Catastrophic earthquakes happened just as often in past human history as they do today. Earthquakes shattered stone-walled cities in the ancient world, sometimes hastening the ends of civilizations. Earthquakes destroyed Knossos, Chattusas, and Mycenae, ancient cities in Europe located in tectonically active mountain ranges. Scribes have documented earthquakes in the chronicles of ancient countries. An earthquake is recorded in the Bible in the Book of Zachariah, and the Apostle Paul wrote that he escaped from jail when the building fell apart around him during an earthquake.

Many faults are located in California because two large plates are sliding past each other there. Of the 15 largest recorded earthquakes ever to hit the continental United States, eight have occurred in California, according to the United States **Geological Survey** (USGS). The San Francisco earthquake of 1906 is perhaps the most famous. It struck on April 4, 1906, killing an estimated 3,000 people, injuring thousands, and causing $524 million in property loss. Many of the casualties and much of the damage resulted from the ensuing fires. This earthquake registered a 7.7 magnitude on the Richter Scale and 11 on the Mercalli Scale. Four other devastating earthquakes have occurred in California in the twentieth century: 1933 in Long Beach, 1971 in the San Fernando Valley, 1989 in the San Francisco Bay area, and 1994 in Los Angeles.

The Long Beach earthquake struck on March 10, 1933, killing 120, injuring hundreds, and causing more than $50 million in property damage. It led to the passage of the state's Field Act, which established strict building code standards designed to make structures better able to withstand strong earthquakes.

Centered about 30 mi (48 km) north of downtown Los Angeles, the San Fernando earthquake killed 65, injured more than 2,000, and caused an estimated $505 million in property damage. The quake hit on February 9, 1971, and registered 6.5 on the Richter Scale and 11 on the Mercalli Scale. Most of the deaths occurred when the Veterans Administration Hospital in San Fernando collapsed.

The Loma Prieta earthquake occurred on October 18, 1989, in the Santa Cruz Mountains about 62 mi (100 km) south of San Francisco. It killed 63, injured 3,757, and caused an estimated $6 billion in property damage, mostly

in San Francisco, Oakland, and Santa Cruz. The earthquake was a 6.9 on the Richter Scale and 9 on the Mercalli Scale.

The Northridge earthquake that struck Los Angeles on January 17, 1994, killed 72, injured 11,800, and caused an estimated $40 billion in damage. It registered 6.7 on the Richter Scale and 9 on the Mercalli Scale. It was centered about 30 mi (48 km) northwest of downtown Los Angeles.

In the past 100 years, Alaska has had many more severe earthquakes than California. However, they have occurred in mostly sparsely populated areas, so deaths, injuries, and damage have been light. Of the 15 strongest earthquakes ever recorded in the 50 states, 10 have been in Alaska, with the strongest registering a 9.2 (the second strongest ever recorded in the world) on the Richter Scale and 12 on the Mercalli Scale. It struck the Anchorage area on March 28, 1964, killing 125 (most from a tsunami or tidal wave caused by the earthquake), injuring hundreds, and causing $311 million in property damage.

The strongest earthquake ever recorded in the world registered 9.5 on the Richter scale and 12 on the Mercalli Scale. It occurred on May 22, 1960, and was centered off the coast of Chile. It killed 2,000, injured 3,000, and caused $675 million in property damage. A resulting tsunami caused death, injuries, and significant property damage in Hawaii, Japan, and the West Coast of the United States.

Every major earthquake raises the question of whether scientists will ever be able to predict exactly when and where one will strike. Today, scientists can only make broad predictions. For example, scientists believe there is at least a 50% chance that a devastating earthquake will strike somewhere along the San Andreas fault within the next 100 years. A more precise prediction is not yet possible. However, scientists in the United States and Japan are working on ways they might be able to make predictions more specific.

Ultra sensitive instruments placed across faults at the surface can measure the slow, almost imperceptible movement of fault blocks. This measurement records the great amount of potential energy stored at the fault boundary. In some areas, small earthquakes called foreshocks that precede a larger earthquake may help seismologists predict the larger earthquake. In other areas where seismologists believe earthquakes should be occurring but are not, this discrepancy between what is expected and what is observed may be used to predict an inevitable large-scale earthquake.

Other instruments measure additional fault-zone phenomena that seem to be related to earthquakes. The rate at which **radon** gas issues from rocks near faults has been observed to change before an earthquake. The properties of the rocks themselves (such as their ability to conduct electricity) have been observed to change as the tectonic force exerted on them slowly alters the rocks of the fault zone between earthquakes. Unusual animal behavior has been reported before many earthquakes, and research into this phenomenon is a legitimate area of scientific inquiry, even though no definite answers have been found.

Techniques of studying earthquakes from space are also being explored. Scientists have found that ground displacements cause waves in the air that travel into the ionosphere and disturb electron densities. By using the network of satellites and ground stations that are part of the Global Positioning System (GPS), and data about the ionosphere that is already being collected, scientists may better understand the energy released from earthquakes. This may help scientists to predict them.

Earthwatch

Earthwatch is a non-profit institution that provides paying volunteers to help scientists around the world conduct field research on environmental and cultural projects. It is one of the world's largest private sponsors of field research expeditions. Its mission is "to improve human understanding of the planet, the diversity of its inhabitants, and the processes which affect the quality of life on earth" by working "to sustain the world's **environment**, monitor global change, conserve endangered habitats and **species**, explore the vast heritage of our peoples, and foster world health and international cooperation."

The group carries out its work by recruiting volunteers to serve in an environmental EarthCorps and to work with research scientists on important environmental issues. The volunteers, who pay from $800 to over $2,500 to join two- or three-week expeditions to the far corners of the globe, gain valuable experience and knowledge on situations that affect the earth and human welfare.

By 2002, Earthwatch has sponsored over 1,180 projects in 50 countries around the world. By the end of the year it expects to have mobilized 4,300 volunteers, ranging in ages from 16 to 85, on 780 research teams. They will address such topics as **tropical rain forest ecology** and **conservation**; marine studies (ocean ecology); geosciences (climatology, geology, oceanography, glaciology, volcanology, paleontology); life sciences (**wildlife management**, biology, botany, ichthyology, herpetology, mammalogy, ornithology, primatology, zoology); social sciences (agriculture, economic anthropology, development studies, nutrition, public health); and art and archaeology (architecture, archaeoastronomy, ethnomusicology, folklore).

Since it was founded in 1971, Earthwatch has organized over 60,000 EarthCorps volunteers, who have contributed over $22 million and more than four million hours on some 1,500 projects in 150 countries and 36 states. No special skills are needed to be part of an expedition, and anyone 16 years or older can apply. Scholarships for students and teachers are also available. Earthwatch's affiliate, The Center for Field Research, receives several hundred grant applications and proposals every year from scientists and scholars who need volunteers to assist them on study expeditions.

Earthwatch publishes *Earthwatch* magazine six times a year, describing its research work in progress and the findings of previous expeditions. The group has offices in Los Angeles, Oxford, Melbourne, Moscow, and Tokyo and is represented in all 50 American states as well as in Germany, Holland, Italy, Spain, and Switzerland by volunteer field representatives.

Eastern European pollution

Between 1987 and 1992 the disintegration of Communist governments of Eastern Europe allowed the people and press of countries from the Baltic to the Black Sea to begin recounting tales of life-threatening **pollution** and disastrous environmental conditions in which they lived. Villages in Czechoslovakia were black and barren because of **acid rain**, **smoke**, and **coal** dust from nearby factories. Drinking water from Estonia to Bulgaria was tainted with toxic **chemicals** and untreated sewage. Polish garden vegetables were inedible because of high **lead** and **cadmium** levels in the soil. Chronic health problems were endemic to much of the region, and none of the region's new governments had the spare cash necessary to alleviate their environmental liabilities.

The air, **soil**, and **water pollution** exposed by new environmental organizations and by a newly vocal press had its roots in Soviet-led efforts to modernize and industrialize Eastern Europe after 1945. (Often the term "Central Europe" is used to refer to Poland, Czech Republic, Slovakia, Hungary, Yugoslavia, and Bulgaria, and "Eastern Europe" to refer to the Baltic states, Belarus, and Ukraine. For the sake of simplicity, this essay uses the latter term for all these states.) Following Stalinist theory that modernization meant industry, especially heavy industries such as coal mining, steel production, and chemical manufacturing, Eastern European leaders invested heavily in industrial buildup. Factories were often built in resource-poor areas, as in traditionally agricultural Hungary and Romania, and they rarely had efficient or clean technology. Production quotas generally took precedence over health and environmental considerations, and billowing smokestacks were considered symbols of national progress. Emission controls on smokestacks and waste **effluent** pipes were, and are, rare. Soft, brown lignite coal, cheap and locally available, was the main fuel source. Lignite contains up to 5% sulfur and produces high levels of **sulfur dioxide**, **nitrogen oxides**, particulates, and other pollutants that contaminate air and soil in population centers, where many factories and **power plants** were built. The region's **water quality** also suffers, with careless disposal of toxic industrial wastes, untreated urban waste, and **runoff** from chemical-intensive agriculture.

By the 1980s the effects of heavy industrialization began to show. Dependence on lignite coal led to sulfur dioxide levels in Czechoslovakia and Poland eight times greater than those of Western Europe. The industrial triangle of Bohemia and Silesia had Europe's highest concentrations of ground-level **ozone**, which harms human health and crops. Acid rain, a result of industrial **air pollution**, had destroyed or damaged half of the forests in the former East Germany and the Czech Republic. Cities were threatened by outdated factory equipment and aging chemical storage containers and pipelines, which leaked **chlorine**, aldehydes, and other noxious gases. People in cities and villages experienced alarming numbers of **birth defects** and short life expectancies. Economic losses, from health care

expenses, lost labor, and production inefficiency further handicapped hard-pressed Eastern European governments.

Popular protests against environmental conditions crystallized many of the movements that overturned Eastern and Central European governments. In Latvia, exposés on **petrochemical poisoning** and on environmental consequences of a hydroelectric project on Daugava River sparked the Latvian Popular Front's successful fight for independence. Massive campaigns against a proposed dam on the Danube River helped ignite Hungary's political opposition in 1989. In the same year, Bulgaria's Ecoglasnost group held Sofia's first non-government rally since 1945. The Polish Ecological Club, the first independent environmental organization in Eastern Europe, assisted the Solidarity movement in overturning the Polish government in the mid-1980s.

Citizens of these countries rallied around environmental issues because they had first-hand experience with the consequences of pollution. In Espenhain, of former East Germany, 80% of children developed chronic **bronchitis** or heart ailments before they were eight years old. Studies showed that up to 30% of Latvian children born in 1988 may have suffered from birth defects, and both children and adults showed unusually high rates of **cancer**, **leukemia**, skin diseases, bronchitis, and asthma. Czech children in industrial regions had acute **respiratory diseases**, weakened immune systems, and retarded bone development, and concentrations of lead and cadmium were found in children's hair. In the industrial regions of Bulgaria skin diseases were seven times more common than in cleaner areas, and cases of rickets and liver diseases were four times as common. Much of the air and soil contamination that produced these symptoms remains today and continues to generate health problems.

Water pollution is at least as threatening as air and soil pollution. Many cities and factories in the region have no facilities for treating **wastewater** and sewage. Existing treatment facilities are usually inadequate or ineffective. Toxic waste dumps containing old and rusting barrels of hazardous materials are often unmonitored or unidentified. Chemical **leaching** from poorly monitored waste sites threatens both surface water and **groundwater**, and water clean enough to drink has become a rare commodity. In Poland untreated sewage, mine **drainage**, and factory effluents make 95% of water unsafe for drinking. At least half of Polish rivers are too polluted, by government assessment, even for industrial use. According to government officials, 70% of all rivers in the industrial Czech region of Bohemia are heavily polluted, 40% of wastewater goes untreated, and nearly a third of the rivers have no fish. In Latvia's port town of Ventspils, heavy oil lies up to 3 ft (1 m) thick on the river bottom. Phenol levels in the nearby Venta River exceed official limits by 800%.

Few pollution problems are geographically restricted to the country in which they were generated. Shared rivers and aquifers and regional weather patterns carry both airborne and water-borne pollutants from one country to another. The Chernobyl nuclear reactor disaster, which spread radioactive gases and particulates from Belarus across northern Europe and the Baltic Sea to northern Norway and Sweden is one infamous example of trans-border pollution, but other examples are common. The town of Ruse, Bulgaria has long been contaminated by chlorine gas emissions from a Romanian plant just across the Danube. Protests against this poisoning have unsettled Bulgarian and Romanian relations since 1987. Toxic wastes flowing into the Baltic Sea from Poland's Vistula River continue to endanger fisheries and shoreline habitats in Sweden, Germany, and Finland.

The Danube River is a particularly critical case. Accumulating and concentrating urban and industrial waste from Vienna to the Black Sea, this river supports industrial complexes of Austria, Czechia, Hungary, Croatia, Serbia, Bulgaria, and Romania. Before the Danube leaves Budapest, it is considered unsafe for swimming. Like other rivers, the Danube flows through a series of industrial cities and mining regions, each river uniting the pollution problems of several countries. Each city and farm along the way uses the contaminated water and contributes some pollutants of its own. Also like other rivers, the Danube carries its toxic load into the sea, endangering the marine environment.

Western countries from Sweden to the United States have their share of pollution and environmental disasters. The Rhine and the Elbe have disastrous **chemical spills** like those on the Danube and the Vistula. Like recent communist regimes, most western business leaders would prefer to disregard environmental and human health considerations in their pursuit of production quotas. Yet several factors set apart environmental conditions in Eastern Europe. Aside from its aged and outdated equipment and infrastructure, Eastern Europe is handicapped by its compressed geography, intense urbanization near factories, a long-standing lack of information and accurate records on environmental and health conditions, and severe shortages of clean-up funds, especially hard currency.

Eastern Europe's dense settlement crowds all the industrial regions of the Baltic states, Poland, the Czech and Slovak republics, and Hungary into an area considerably smaller than Texas but with a much higher population. This industrial zone lies adjacent to crowded manufacturing regions of Western Europe. In this compact region, people farm the same fields and live on the same mountains that are stripped for mineral extraction. Cities and farms rely on aquifers and rivers that receive factory effluent and **pesticide**

runoff immediately upstream. Furthermore, post-1945 industrialization gathered large labor forces into factory towns more quickly than adequate infrastructure could be built. Expanding urban populations had little protection from the unfiltered pollutants of nearby furnaces. At the same time that many Eastern Europeans were eye witnesses to environmental transgressions, little public discussion about the problem was possible. Official media disliked publicizing health risks or the destruction of forests, rivers, and lakes. Those **statistics** that existed were often unreliable. Air and water quality data were collected and reported by industrial and government officials, who could not afford bad test results.

Now that environmental conditions are being exposed, cleanup efforts remain hampered by a shortage of funding. Poland's long-term environmental restoration may cost $260 billion, or nearly eight times the country's annual GNP in the mid-1980s. Efforts to cut just sulfur dioxide emissions to Western standards would cost Poland about $2.4 billion a year. Hungary, with a mid-1980s GNP of $25 billion, could begin collecting and treating its sewage for about $5 billion. Cleanup in the port of Ventspils, Latvia, is expected to cost 3.6 billion rubles and $1.5 billion in hard currency. East German air, soil, and water **remediation** get a boost from their western neighbors, but the bill is expected to run between $40 and $150 billion.

Ironically, East European leaders see little choice for raising this money aside from expanded industrial production.Meanwhile, business leaders urge production expansion for other capital needs. Some Western investment in cleanup work has begun, especially on the part of such countries as Sweden and Germany, which share rivers and seas with polluting neighbors. Already in 1989 Sweden had begun work on water quality monitoring stations along Poland's Vistula River, which carries pollutants into the Baltic Sea. Capital necessary to purchase mitigation equipment, improve factory conditions, rebuild rusty infrastructure, and train environmental experts will probably be severely limited for decades to come, however.

Meanwhile, western investors are flocking to Eastern and Central Europe in hopes to build or rebuild business ventures for their own gain. The region is seen as one of quick growth and great potential. Manufacturers in heavy and light industries, automobiles, power plants, and home appliances are coming from Western Europe, North America, and Asia. From textile manufacturing to agribusiness, outside investors hope to reshape Eastern economies. Many Western companies are improving and updating equipment and adding **pollution control** devices. In a **climate** of uncertain regulation and rushed economic growth, however, no one knows if the region's new governments will be able or willing to enforce environmental safeguards or if the new investors will take advantage of weak regulations and poor enforcement as did their predecessors.

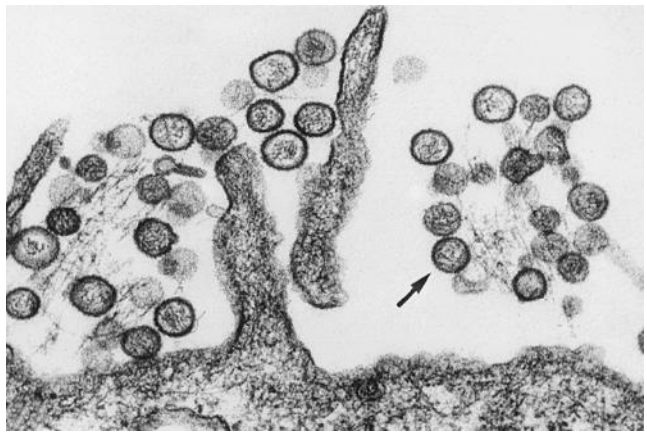
Ebola

Ebola is a highly deadly viral hemorrhagic disease. As the disease progresses, the walls of blood vessels break down and blood gushes from every tissue and organ. The disease is caused by the Ebola **virus**, named after the river in Zaire (now the Democratic Republic of Congo) where the first known outbreak occurred. The disease is extremely contagious and exceptionally lethal. Where a 10% **mortality** rate is considered high for most infectious diseases, Ebola can kill up to 90% of its victims, usually within only a few days after exposure. It seems to take direct contact with contaminated blood or bodily fluids to catch the disease. Health personnel and caregivers are often the most likely to be infected. Even after a patient has died, preparing the body for a funeral can be deadly for families members.

The Ebola virus is one of two members of a family of RNA viruses called the Filoviridae. The other filovirus causes Marburg fever, an equally contagious and lethal hemorrhagic disease, named after a German town where it was first contracted by laboratory workers who handled imported monkeys infected with the virus. Together with members of three other families (arenaviruses, bunyanviruses, and flaviviruses), these viruses cause a group of deadly, episodic diseases including Lassa fever, Rift Valley fever, Bolivian fever, and Hanta or Four-Corners fever (named after the region of the southwestern United States where it was first reported).



The viruses associated with most of these emergent, hemorrhagic fevers are zoonotic. That means a **reservoir** of pathogens naturally resides in an animal host or arthropod vector. We don't know the specific host or vector for Ebola, but monkeys and other primates can contract related diseases. People who initially become infected with Ebola often

have been involved in killing, butchering, and eating gorillas, chimps, or other primates. Why the viruses remain peacefully in their hosts for many years without causing much more trouble than a common cold, but then erupt sporadically and unpredictably into terrible human epidemics, is a new and growing question in **environmental health**.

The geographical origin for Ebola is unknown, but all recorded outbreaks have occurred in or around Central Africa, or in animals or people from this area. Ebola appears every few years in Africa. Confirmed cases have occurred in the Democratic Republic of the Congo, Gabon, Sudan, Uganda, and the Ivory Coast. No case of the disease in humans has ever been reported in the United States, but a variant called Ebola-Reston virus killed a number of monkeys in a research facility in Reston, Virginia. A fictionalized account of this outbreak was made into a movie called "Hot Zone." There probably are isolated cases in remote areas that go unnoticed. In fact, the disease may have been occurring in secluded villages deep in the jungle for a long time without outside attention. The most recent Ebola outbreak was in 2002 when about 100 people died in a remote part of Gabon and an adjacent area in Congo.

The worst epidemic of Ebola in humans occurred in 1995, in Kikwit, Zaire (now the Democratic Republic of Congo). Although many more people died in Kikwit that in any other outbreak, in many ways, the medical and social effects of the epidemic there was typical of what happens elsewhere. The first Kikwit victim was a 36-year-old laboratory technician named Kimfumu, who checked into a medical clinic complaining of a severe headache, stomach pains, fever, dizziness, weakness, and exhaustion. Surgeons did an exploratory operation to try to find the cause of his illness. To their horror, they found his entire gastrointestinal tract was necrotic and putrefying. He bled uncontrollably, and within hours was dead. By the next day, the five medical workers who had cared for Kimfumu, including an Italian nun who assisted in the operation, began to show similar symptoms, including high fevers, fatigue, bloody diarrhea, rashes, red and itchy eyes, vomiting, and bleeding from every body orifice. Less than 48 hours later, they, too, were dead, and the disease was spread throughout the city of 600,000.

As panicked residents fled into the bush, government officials responded to calls for help by closing off all travel—including humanitarian aid—into or out of Kikwit, about 250 mi (400 km) from Kinshasa, the national capitol. Fearful neighboring villages felled trees across the roads to seal off the pestilent city. No one dared enter houses where dead corpses rotted in the intense tropical heat. Boats plying the adjacent Kwilu River refused to stop to take on or **discharge** passengers or cargo. Food and clean water became scarce. Hospitals could hardly function as medicines and medical personal became scarce. Within a few weeks, about 400 people in Kikwit had contracted the disease and at least 350 were dead. Eventually, the epidemic dissipated and disappeared. It isn't known why the infection rate dropped or what residents might do to prevent a further reappearance of the terrible disease.

An electron micrograph of the ebola virus and the hanta virus. (Delmar Publishers Inc. Reproduced by permission.)

Because health professionals are among the most likely to be exposed to Ebola when an outbreak occurs, it is important for them to have access to rapid antigen or antibody assays and isolation facilities to prevent further spread of the virus. Unfortunately, these advanced medical procedures generally are lacking in the African hospitals where the disease is most likely to occur. There is no standard treatment for Ebola other than supportive therapy. Patients are given replacement fluids and electrolytes, and oxygen levels and blood pressure are stabilized as much as possible. During the Kikwit outbreak, eight patients were given blood of individuals who had been infected with the virus but who had recovered. It was hoped that their blood might have antibodies to fight the infection. Seven of the eight transfusion patients survived, but the number tested is too small to be sure this was statistically significant. There is no vaccine or other antiviral drug available to prevent or halt an infection.

Several factors seem to be contributing to the appearance and spread of highly contagious diseases such as Ebola and Marburg fevers. With 6 billion people now inhabiting the planet, human densities are much higher enabling germs to spread further and faster than ever before. Expanding populations push people into remote areas where they encounter new pathogens and **parasites**. Environmental change is occurring on a larger scale: cutting forests, creating unhealthy urban surroundings, and causing global-climate change, among other things. Elimination of predators and

habitat changes favor disease-carrying organisms such as mice, rats, cockroaches, and mosquitoes.

Another important factor in the spread of many diseases is the speed and frequency of modern travel. Millions of people go every day from one place to another by airplane, boat, train, or **automobile**. Very few places on earth are more than 24 hours by jet plane from any other place. In 2001, a woman flying from the Congo arrived in Canada delirious with a high fever. She didn't, in fact, have Ebola, but Canadian officials were concerned about the potential spread of the disease. Finding ways to cure Ebola and prevent its spread may be more than simply a humanitarian concern for its victims in Central Africa. It might be very much in our own self-interest to make sure that this terrible disease doesn't cross our borders either accidentally or intentionally through actions of a terrorist organization.

Eco Mark

The Japanese environmental label known as "Eco Mark" is a relatively new addition to a worldwide effort to designate products that are environmentally friendly. The Eco Mark program was launched in February 1989. The symbol is two arms embracing the world, symbolizing the protection of the earth. The arms create the letter "e" with the earth in the center. Indicating English as the international language, the Japanese use "e" to stand for **environment**, earth, and **ecology**.

The Japanese program is entirely government funded, although a small fee is charged to applicant industries. The annual fee is based on the retail price of a product, not annual product sales as is the case for other national green labeling programs. Products ranging in price from $0–7 are charged an annual fee of $278.00; from $7–70 are charged an annual fee of $417; from $70–700 are charged an annual fee of $556; and products priced over $700 are charged an annual fee of $700. Obviously, those products that are low in price and high in volume sold are most likely to apply for the Eco Mark label.

The Eco Mark program seeks to sanction products with the following four qualities: 1) minimal environmental impact from use; 2) significant potential for improvement of the environment by using the product; 3) minimal environmental impact from disposal after use; and 4) other significant contributions to improve the environment.

In addition, labeled products must comply with the following guidelines: 1) appropriate environmental **pollution control** measures are provided at the stage of production; 2) ease of treatment for disposal of product; 3) energy or resources are conserved with use of product; 4) compliance with laws, standards, and regulations pertaining to quality and safety; 5) price is not extraordinarily higher than comparable products.

The Environment Association, supervised by the Japanese Environment Agency, is in charge of the Eco Mark program. All technical, research, and administrative support is provided by the government. The labeling program is guided by two committees.

The Eco Mark Promotion Committee acts primarily in a supervisory capacity, approving the guidelines for the program's operation and advising on operations, including evaluation of the program categories and criteria. The promotion committee consists of nine members representing industry, marketing groups, local governments, environmental agencies, and the National Institute for Environmental Studies.

In addition to the Promotion Committee there is a committee for approval of products. This committee consists of five members with representation from the science community, the consumer protection community, and, as in the Promotion Committee, a representative each from the Environment Agency and the National Institute for Environmental Studies. The Japanese program is completely voluntary for manufacturers. Once a product is approved by the Approval Committee, a two-year renewable licensing contract for the use of the Eco Mark is signed with the Japan Environment Association.

The Eco Mark program is very goal-oriented and places great emphasis on overall environmental impact. The attention to production impacts, as well as use and disposal impacts, makes the program unique within the family of green labeling programs worldwide. Its primary goals are to encourage innovation by industry and elevate the environ-

mental awareness and consumer behavior of the Japanese people in order to enhance environmental quality.

Japan's Environment Agency claims that responses from consumer and environmental organizations have been positive, while industry has been less than enthusiastic. In fact, the Eco Mark only covered seven products in 1989 and now covers over 5,000. Some scientists have voiced concern over the superficiality of the analysis procedure used to determine Eco Mark products. However, despite criticisms, the Japanese Eco Mark program is a strong national effort to encourage environmentally sound decisions and protect the environment for **future generations** in that country. *See also* Environmental policy; Green packaging; Green products; Precycling; Recycling; Reuse; Waste reduction

Ecoanarchism

see **Ecoterrorism**

Ecocide

Any substance that enters an ecological system, spreads throughout that system, and kills enough members of the **ecosystem** to disrupt its structure and function. For example, on July 14, 1991, a freight train carrying the **pesticide** metam sodium fell off a bridge near Dunsmuir, California, spilling its contents into the Sacramento River. When mixed with water this pesticide becomes highly poisonous, and all animal life for some distance downstream of the spill site was killed.

Ecofeminism

Coined in 1974 by the French feminist Francoise d'Eaubonne, ecofeminism, or ecological feminism, is a recent movement that asserts that the **environment** is a feminist issue and that feminism is an environmental issue. The term ecofeminism has come to describe two related movements operating at somewhat different levels: (1) the grassroots, women-initiated activism aimed at eliminating the oppression of women and **nature**; and (2) a newly emerging branch of philosophy that takes as its subject matter the foundational questions of meaning and justification in feminism and **environmental ethics**. The latter, more properly termed ecofeminist philosophy, stands in relation to the former as theory stands to practice. Though closely related, there nevertheless remain important methodological and conceptual distinctions between action- and theory-oriented ecofeminism.

The ecofeminist movement developed from diverse beginnings, nurtured by the ideas and writings of a number of feminist thinkers, including Susan Griffin, Carolyn Merchant, Rosemary Radford Ruether, Ynestra King, Ariel Salleh, and Vandana Shiva. The many varieties of feminism (liberal, marxist, radical, socialist, etc.) have spawned as many varieties of ecofeminism, but they share a common ground. As described by Karren Warren, a leading ecofeminist philosopher, ecofeminists believe that there are important connections—historical, experiential, symbolic, and theoretical—between the domination of women and the domination of nature. In the broadest sense, then, ecofeminism is a distinct social movement that blends theory and practice to reveal and eliminate the causes of the dominations of women and of nature.

While ecofeminism seeks to end all forms of oppression, including racism, classism, and the abuse of nature, its focus is on gender bias, which ecofeminists claim has dominated western culture and led to a patriarchal, masculine value-oriented hierarchy. This framework is a socially constructed mindset that shapes our beliefs, attitudes, values, and assumptions about ourselves and the natural world.

Central to this patriarchal framework is a pattern of thinking that generates normative dualisms. These are created when paired complementary concepts such as male/female, mind/body, culture/nature, and reason/emotion are seen as mutually exclusive and oppositional. As a result of socially-entrenched gender bias, the more "masculine" member of each dualistic pair is identified as the superior one. Thus, a value hierarchy is constructed which ranks the masculine characteristics above the feminine (e.g., culture above nature, man above woman, reason above emotion). When paired with what Warren calls a "logic of domination," this value hierarchy enables people to justify the subordination of certain groups on the grounds that they lack the "superior" or more "valuable" characteristics of the dominant groups. Thus, men dominate women, humans dominate nature, and reason is superior to emotion. Within this patriarchal conceptual framework, subordination is legitimized as the necessary oppression of the inferior. Until we reconceptualize ourselves and our relation to nature in non-patriarchal ways, ecofeminists maintain, the continued dual denigration of women and nature is assured.

Val Plumwood, an Australian ecofeminist philosopher, has traced the roots of the development of the oppression of women and the exploitation of nature to three points, the first two points sharing historical origins, the third having its genesis in human psychology. In the first of these histori-

cal women-nature connections, dualism has identified higher and lower "halves." The lower halves, seen as possessing less or no **intrinsic value** relative to their polar opposites, are instrumentalized and subjugated to serve the needs of the members of the "higher" groups. Thus, due to their historical association and supposedly shared traits, women and nature have been systematically devalued and exploited to serve the needs of men and culture.

The second of these historical women-nature connections is said to have originated with the rise of mechanistic science before and during the Enlightenment period. According to some ecofeminists, dualism was not necessarily negative or hierarchical; however, the rise of modern science and technology, reflecting the transition from an organic to a mechanical view of nature, gave credence to a new logic of domination. Rationality and scientific method became the only socially sanctioned path to true knowledge, and individual needs gained primacy over community. On this fertile **soil** were sown the seeds for an ethic of exploitation.

A third representation of the connections between women and nature has its roots in human psychology. According to this account, the features of masculine consciousness which allow men to objectify and dominate are the result of sexually-differentiated personality development. As a result of women's roles in both creating and maintaining/nurturing life, women develop "softer" ego boundaries than do men, and thus they generally maintain their connectedness to other humans and to nature, a connection which is reaffirmed and recreated generationally. Men, on the other hand, psychologically separate both from their human mothers and from Mother Earth, a process which results in their desire to subdue both women and nature in a quest for individual potency and transcendence. Thus, sex differences in the development of self/other identity in childhood are said to account for women's connectedness with, and men's alienation from, both humanity and nature.

Ecofeminism has attracted criticism on a number of points. One is the implicit assumption in certain ecofeminist writings that there is some connection between women and nature that men either do not possess or cannot experience. And, why female activities such as birth and childcare should be construed as more "natural" than some traditional male activities remains to be demonstrated. This assumption, though, has left some ecofeminists open to charges of having constructed a new value hierarchy to replace the old, rather than having abandoned hierarchical conceptual frameworks altogether. Hints of hierarchical thinking can be found in such ecofeminist practices as goddess worship and in the writings of some radical ecofeminists who advocate the abandonment of reason altogether in the search for an appropriate human-nature relationship. Rather than having destroyed gender bias, some ecofeminists are accused of merely attempting to reverse its polarity, possibly creating new, subtle forms of women's oppression. Additionally, some would argue that ecofeminism runs the risk of oversimplification in suggesting that all struggles between dominator and oppressed are one and the same and thus can be won through unity.

A lively debate is currently underway concerning the compatibility of ecofeminism with other major theories or schools of thought in environmental philosophy. For instance, discussions of the similarities and differences between ecofeminism and **deep ecology** occupy a large portion of the recent theoretical literature on ecofeminism. While deep ecologists are primarily concerned with anthropocentrism as the primary cause of our destruction of nature, ecofeminists point instead to androcentrism as the key problem in this regard. Nevertheless, both groups aim for the expansion of the concept of "self" to include the natural world, for the establishment of a biocentric egalitarianism, and for the creation of connection, wholeness, and empathy with nature.

Given the newness of ecofeminism as a theoretical discipline, it is no surprise that the nature of ecofeminist ethics is still emerging. A number of different feminist-inspired positions are gaining prominence, including feminist **animal rights**, feminist environmental ethics based on caregiving, feminist **social ecology**, and feminist **bioregionalism**. Despite the apparent lack of a unified and overarching environmental philosophy, all forms of ecofeminism do share a commitment to developing ethics which do not sanction or encourage either the domination of any group of humans or the abuse of nature. Already, ecofeminism has shown us that issues in environmental ethics and philosophy cannot be meaningfully or adequately discussed apart from considerations of social domination and control. If ecofeminists are correct, then a fundamental reconstruction of the value and structural relations of our society, as well as a reexamination of the underlying assumptions and attitudes, is necessary.

Ecojustice

The concept of ecojustice has at least two different usages among environmentalists. The first refers to a general set of attitudes about justice and the **environment** at the center of which is dissatisfaction with traditional theories of justice. With few exceptions (notably a degree of concern about excessive cruelty to animals), anthropocentric and egocentric Western moral and ethical systems have been unconcerned with individual plants and animals, **species**, oceans, **wilderness** areas, and other parts of the **biosphere**, except as they may be used by humans. In general, that which is non-human is viewed mainly as raw material for human uses, largely or completely without moral standing.

Relying upon holistic principles of biocentrism and **deep ecology**, the "ecojustice" alternative suggests that the value of non-human life-forms is independent of the usefulness of the non-human world for human purposes. Antecedents of this view can be found in sources as diverse as Eastern philosophy, Aldo Leopold's "land ethic," Albert Schweitzer's "reverence for life," and Martin Heidegger's injunction to "let beings be." The central idea of ecojustice is that the categories of ethical and moral reflection relevant to justice should be expanded to encompass **nature** itself and its constituent parts, and human beings have an obligation to take the inherent value of other living things into consideration whenever these living things are affected by human actions.

Some advocates of an ecojustice perspective base standards of just treatment on the evident capacity of many life-forms to experience pain. Others assert the equal inherent worth of all individual life-forms. More typically, environmental ethicists assert that all life-forms have at least some inherent worth, and thus deserve moral consideration, although perhaps not the same worth. The practical goals associated with ecojustice include the fostering of **stability** and diversity within and between self-sustaining ecosystems, harmony and balance in nature and within competitive biological systems, and **sustainable development**.

Ecojustice can also refer simply to the linking of environmental concerns with various social justice issues. The advocate of ecojustice typically strives to understand how the logic of a given economic system results in certain groups or classes of people bearing the brunt of **environmental degradation**. This entails, for example, concern with the frequent location of polluting industries and **hazardous waste** dumps near the economically disadvantaged (i.e., those with the least mobility and fewest resources to resist).

In much the same way, ecojustice also involves the fostering of sustainable development in less-developed areas of the globe, so that economic development does not mean the export of polluting industries and other environmental problems to these less-developed areas. An additional point of concern is the allocation of costs and benefits in environmental **reclamation** and preservation—for example, the preservation of Amazonian rain forests affects the global environment and may benefit the whole world, but the costs of this preservation fall disproportionately upon Brazil and the other countries of the region. An advocate of ecojustice would be concerned that the various costs and benefits of development be apportioned fairly. *See also* Biodiversity; Ecological and environmental justice; Environmental ethics; Environmental racism; Environmentalism; Holistic approach

Ecological consumers

Organisms that feed either directly or indirectly on producers, plants that convert **solar energy** into complex organic molecules. Primary consumers are animals that eat plants directly. They are also called herbivores. Secondary consumers are animals that eat other animals. They are also called carnivores. Consumers that eat both plants and animals are omnivores. **Parasites** are a type of consumer that lives in or on the plant or animal on which it feeds. Detrivores (**detritus** feeders and **decomposers**) constitute a specialized class of consumers that feed on dead plants and animals. *See also* Biotic community

Ecological integrity

Ecological (or biological) integrity is a measure of how intact or complete an **ecosystem** is. Ecological integrity is a relatively new and somewhat controversial notion, however, which means that it cannot be defined exactly. Human activities cause many changes in environmental conditions, and these can benefit some **species**, communities, and ecological processes, while causing damages to others at the same time. The notion of ecological integrity is used to distinguish between ecological responses that represent improvements, and those that are degradations.

Challenges to ecological integrity

Ecological integrity is affected by changes in the intensity of environmental stressors. Environmental stressors can be defined as physical, chemical, and biological constraints on the productivity of species and the processes of ecosystem development. Many environmental stressors are associated

with the activities of humans, but some are also natural factors. Environmental stressors can exert their influence on a local scale, or they may be regional or even global in their effects. Stressors represent environmental challenges to ecological integrity.

Environmental stressors are extremely complex, but they can be categorized in the following ways:

(1) Physical stressors are associated with brief but intense exposures to kinetic energy. Because of its acute, episodic nature, this represents a type of disturbance. Examples include volcanic eruptions, windstorms, and explosions; (2) **Wildfire** is another kind of disturbance, characterized by the **combustion** of much of the **biomass** of an ecosystem, and often the deaths of the dominant plants; (3) **Pollution** occurs when **chemicals** are present in concentrations high enough to affect organisms and thereby cause ecological changes. Toxic pollution may be caused by such gases as **sulfur dioxide** and **ozone**, metals such as **mercury** and **lead**, and pesticides. Nutrients such as phosphate and nitrate can affect ecological processes such as productivity, resulting in a type of pollution known as eutrophication; (4) Thermal stress occurs when releases of heat to the **environment** cause ecological changes, as occurs near natural hot-water vents in the ocean, or where there are industrial discharges of warmed water; (5) Radiation stress is associated with excessive exposures to ionizing energy. This is an important stressor on mountaintops because of intense exposures to **ultraviolet radiation**, and in places where there are uncontrolled exposures to radioactive wastes; (6) Climatic stressors are associated with excessive or insufficient regimes of temperature, moisture, solar radiation, and combinations of these. **Tundra** and deserts are climatically stressed ecosystems, while tropical rain forests occur in places where the climatic regime is relatively benign; (7) Biological stressors are associated with the complex interactions that occur among organisms of the same or different species. Biological stresses result from **competition**, herbivory, predation, parasitism, and disease. The harvesting and management of species and ecosystems by humans can be viewed as a type of biological stress.

All species and ecosystems have a limited capability for tolerating changes in the intensity of environmental stressors. Ecologists refer to this attribute as **resistance**. When the limits of tolerance to **environmental stress** are exceeded, however, substantial ecological changes are caused.

Large changes in the intensity of environmental stress result in various kinds of ecological responses. For example, when an ecosystem is disrupted by an intense disturbance, there will be substantial **mortality** of some species and other damages. This is followed by recovery of the ecosystem through the process of **succession**. In contrast, a longer-term intensification of environmental stress, possibly caused by chronic pollution or **climate** change, will result in longer lasting ecological adjustments. Relatively vulnerable species become reduced in abundance or are eliminated from sites that are stressed over the longer term, and their modified niches will be assumed by more tolerant species. Other common responses of an intensification of environmental stress include a simplification of species richness, and decreased rates of productivity, **decomposition**, and **nutrient** cycling. These changes represent a longer-term change in the character of the ecosystem.

Components of ecological integrity

Many studies have been made of the ecological responses to both disturbance and to longer-term changes in the intensity of environmental stressors. Such studies have, for instance, examined the ecological effects of air or **water pollution**, of the harvesting of species or ecosystems, and the conversion of natural ecosystems into managed agroecosystems. The commonly observed patterns of change in stressed ecosystems have been used to develop indicators of ecological integrity, which are useful in determining whether this condition is improving or being degraded over time. It has been suggested that greater ecological integrity is displayed by systems that, in a relative sense: (1) *are resilient and resistant to changes in the intensity of environmental stress*. Ecological resistance refers to the capacity of organisms, populations, or communities to tolerate increases in stress without exhibiting significant responses. Once thresholds of tolerance are exceeded, ecological changes occur rapidly. **Resilience** refers to the ability to recover from disturbance; (2) *are biodiverse*. **Biodiversity** is defined as the total richness of biological variation, including genetic variation within populations and species, the numbers of species in communities, and the patterns and dynamics of these over large areas; (3) *are complex in structure and function*. The complexity of the structural and functional attributes of ecosystems is limited by natural environmental stresses associated with climate, **soil**, chemistry, and other factors, and also by stressors associated with human activities. As the overall intensity of stress increases or decreases, structural and functional complexity responds accordingly. Under any particular environmental regime, older ecosystems will generally be more complex than younger ecosystems; (4) *have large species present*. The largest species in any ecosystem appropriate relatively large amounts of resources, occupy a great deal of space, and require large areas to sustain their populations. In addition, large species tend to be long-lived, and consequently they integrate the effects of stressors over an extended time. As a result, ecosystems that are affected by intense environmental stressors can only support a few or no large species. In contrast, mature ecosystems occurring in a relatively benign environmental

regime are dominated by large, long-lived species; (5) *have higher-order predators present*. Top predators are sustained by a broad base of **ecological productivity**, and consequently they can only occur in relatively extensive and/or productive ecosystems; (6) *have controlled nutrient cycling*. Ecosystems that have recently been disturbed lose some of their biological capability for controlling the cycling of nutrients, and they may lose large amounts of nutrients dissolved or suspended in stream water. Systems that are not "leaky" of their nutrient capital are considered to have greater ecological integrity; (7) *are efficient in energy use and transfer*. Large increases in environmental stress commonly result in community-level **respiration** exceeding productivity, resulting in a decrease in the standing crop of biomass in the system. Ecosystems that are not losing their capital of biomass are considered to have greater integrity than those in which biomass is decreasing over time; (8) *have an intrinsic capability for maintaining natural ecological values*. Ecosystems that can naturally maintain their species, communities, and other important characteristics, without being managed by humans, have greater ecological integrity. If, for example, a population of a **rare species** can only be maintained by management of its **habitat** by humans, or by a program of captive-breeding and release, then its population, and the ecosystem of which it is a component, are lacking in ecological integrity; (9) *are components of a "natural" community*. Ecosystems that are dominated by non-native, **introduced species** are considered to have less ecological integrity than ecosystems composed of indigenous species.

Indicators (8) and (9) are related to "naturalness" and the roles of humans in ecosystems, both of which are philosophically controversial topics. However, most ecologists would consider that self-organizing, unmanaged ecosystems composed of native species have greater ecological integrity than those that are strongly influenced by humans. Examples of strongly human-dominated systems include agroecosystems, forestry plantations, and urban and suburban areas. None of these ecosystems can maintain their character in the absence of management by humans, including large inputs of energy and nutrients.

Indicators of ecological integrity

Indicators of ecological integrity vary greatly in their intent and complexity. For instance, certain metabolic indicators have been used to monitor the responses by individuals and populations to toxic stressors, as when bioassays are made of **enzyme** systems that respond vigorously to exposures to **dichlorodiphenyl-trichloroethane** (DDT), pentachlorophenols (PCBs), and other **chlorinated hydrocarbons**. Other simple indicators include the populations of **endangered species**; these are relevant to the viability of those species as well as the integrity of the ecosystem of which they are a component. There are also indicators of ecological integrity at the level of landscape, and even global indicators relevant to climate change, depletion of stratospheric ozone, and **deforestation**.

Relatively simple indicators can sometimes be used to monitor the ecological integrity of extensive and complex ecosystems. For example, the viability of populations of spotted owls (*Strix occidentalis*) is considered to be an indicator of the integrity of the old-growth forests in which this endangered species breeds in the western United States. These forests are commercially valuable, and if plans to harvest and manage them are judged to threaten the viability of a population of spotted owls, this would represent an important challenge to the integrity of the **old-growth forest** ecosystem.

Ecologists are also beginning to develop composite indicators of ecological integrity. These are designed as summations of various indicators, and are analogous to such economic indices such as the Dow-Jones Index of stock markets, the Consumer Price Index, and the gross domestic product of an entire economy. Composite economic indicators of this sort are relatively simple to design, because all of the input data are measured in a common way (for example, in dollars). In **ecology**, however, there is no common currency among the many indicators of ecological integrity. Consequently it is difficult to develop composite indicators that ecologists will agree upon.

Still, some research groups have developed composite indicators of ecological integrity that have been used successfully in a number of places and environmental contexts. For instance, the ecologist James Karr and his co-workers have developed composite indicators of the ecological integrity of aquatic ecosystems, which are being used in modified form in many places in North America.

In spite of all of the difficulties, ecologists are making substantial progress in the development of indicators of ecological integrity. This is an important activity, because our society needs objective information about complex changes that are occurring in environmental quality, including degradations of indigenous species and ecosystems. Without such information, actions may not be taken to prevent or repair unacceptable damages that may be occurring.

Increasingly, it is being recognized that human economies can only be sustained over the longer term by ecosystems with integrity. Ecosystems with integrity are capable of supplying continuous flows of such renewable resources as timber, fish, agricultural products, and clean air and water. Ecosystems with integrity are also needed to sustain populations of native species and their natural ecosystems, which must be sustained even while humans are exploiting the resources of the **biosphere**.

Ecological productivity

One of the most important properties of an **ecosystem** is its productivity, which is a measure of the rate of incorporation of energy by plants per unit area per unit time. In terrestrial ecosystems, ecologists usually estimate plant production as the total annual growth—the increase in plant **biomass** over a year. Since productivity reflects plant growth, it is often used loosely as a measure of the organic fertility of a given area.

The flow of energy through an ecosystem starts with the fixation of sunlight by green plants during **photosynthesis**. Photosynthesis supplies both the energy (in the form of chemical bonds) and the organic molecules (glucose) that plants use to make other products in a process known as biosynthesis. During biosynthesis, glucose molecules are rearranged and joined together to become complex carbohydrates (such as cellulose and starch) and lipids (such as fats and plant oils). These products are also combined with **nitrogen**, **phosphorus**, sulfur, and magnesium to produce the proteins, nucleic acids, and pigments required by the plant. The many products of biosynthesis are transported to the leaves, flowers, and roots, where they are stored to be used later.

Ecologists measure the results of photosynthesis as increases in plant biomass over a given time. To do this more accurately, ecologists distinguish two measures of assimilated light energy: gross primary production (GPP), which is the total light energy fixed during photosynthesis, and net primary production (NPP), which is the chemical energy that accumulates in the plant over time.

Some of this chemical energy is lost during plant **respiration** (R) when it is used for maintenance, reproduction, and biosynthesis. The proportion of GPP that is left after respiration is counted as net production (NPP). In an ecosystem, it is the energy stored in plants from net production that is passed up the **food chain/web** when the plants are eaten. This energy is available to consumers either directly as plant tissue or indirectly through animal tissue.

One measure of ecological productivity in an ecosystem is the production efficiency. This is the rate of accumulation of biomass by plants, and it is calculated as the ratio of net primary production to gross primary production. Production efficiency varies among plant types and among ecosystems. Grassland ecosystems which are dominated by nonwoody plants are the most efficient at 60-85%, since grasses and annuals do not maintain a high supporting biomass. On the other end of the efficiency scale are forest ecosystems; they are dominated by trees, and large old trees spend most of their gross production in maintenance. For example, eastern deciduous forests have a production efficiency of about 42%.

Ecological productivity in terrestrial ecosystems is influenced by physical factors such as temperature and rainfall. Productivity is also affected by air and water currents, **nutrient** availability, land forms, light intensity, altitude, and depth. The most productive ecosystems are tropical rain forests, coral reefs, salt marshes and estuaries; the least productive are deserts, **tundra**, and the open sea. *See also* Ecological consumers; Ecology; Habitat; Restoration ecology

[*Neil Cumberlidge Ph.D.*]

Ecological risk assessment

Ecological **risk assessment** is a procedure for evaluating the likelihood that adverse ecological effects are occurring, or may occur, in ecosystems as a result of one or more human activities. These activities may include the alteration and destruction of **wetlands** and other habitats, the introduction of herbicides, pesticides, and other toxic materials into the **environment**, **oil spills**, or the cleanup of contaminated **hazardous waste** sites. Ecological risk assessments consider many aspects of an **ecosystem**, both the biotic plants and animals and the abiotic water, soils, and other elements. Ecosystems can be as small as a pond or stretch of a river or as large as thousands of square miles or lengthy coastlines in which communities exist.

Although closely related to human health risk assessment, ecological risk assessment is not only a newer discipline but also uses different procedures, terminology, and concepts. Both human health and ecological risk assessment provide frameworks for collecting information to define a risk and to help make risk management or regulatory decisions. But human health risk assessment follows four basic steps that were defined in a 1983 by the **National Research Council**: hazard assessment, **dose response** assessment, exposure assessment, and risk characterization. In contrast, ecological risk assessment relies on a *Framework for Ecological Risk Assessment* published by **Environmental Protection Agency** in 1992 as part of a long-term plan to develop ecological risk assessment guidelines. The Framework defines three steps: problem formulation, analysis, and risk characterization.

The problems that human health risk assessments seek to address are clearly defined: **cancer**, **birth defects**, **mortality**, and the like. But the problems that ecological risk assessments tries to understand and deal with are less straightforward. For instance, a major challenge ecological **risk assessors** face is distinguishing natural changes in an ecosystem from changes caused by human activities and defining what changes are unacceptable. As a result, the initial problem formulation step of an ecological risk assessment requires extensive discussions between risk assessors and risk managers to define "ecological significance," a key concept in ecological risk assessment. Because it is not immediately clear whether an ecological change is positive or negative—unlike cancer or birth defects, which are known to be adverse—judgments must be made early in the assessment about whether a change is significant and whether it will alter a socially valued ecological condition. For example, **Lake Erie** was declared "dead" in the 1960s as a result of phosphorous loadings from cities and farms. But, in fact, there were more fish in the lake after it was "dead" than before; however, these fish were carp, suckers, catfish, not the walleyed pike, yellow perch, and other fish that had made Lake Erie one of the highest valued freshwater sport fishing lakes in the United States. More recently, with **pollution** inputs greatly reduced, the lake has recovered much of its former productivity. Choosing one ecological condition over the other is a social value of the kind fundamental to ecological risk assessment problem formulation. Once judgments have been made about what values to protect, analysis can proceed to examine the "stressors" that ecosystems are exposed to and a characterization can be made of the "ecological effects" likely from such stressors.

Since 1989, EPA has held workshops on "ecological significance" and other technical issues pertaining to ecological risk assessment and has published the results of its workshops in a series of reports and case studies. In 1996, EPA proposed its first ecological risk assessment guidelines, with final guidelines published in May of 1998. Overall, the direction of ecological protection priorities has been away from earlier concerns with narrow goals (e.g., use of commercially valuable **natural resources**) toward broader interest in protecting natural areas such as National Parks and Scenic Rivers for both present and **future generations** to enjoy.

Ecological Society of America

The Ecological Society of America (ESA), representing 7,500 ecological researchers in the United States, Canada, Mexico, and 62 other countries, was founded in 1915 as a non-profit, scientific organization and today is the nation's leading professional society of ecologists. Members include ecologists from academia, government agencies, industry, and non-profit organizations. In pursuing its goal of promoting "the responsible application of ecological principles to the solution of environmental problems," the Society publishes reports, membership research, and three scientific journals a year, and it provides expert testimony to Congress. In addition, ESA holds a conference every summer attended by more than 3,000 scientists and students at which members present the latest ecological research. The Society's three journals are: *Ecology* (eight issues per year), *Ecological Monographs* (four issues per year), and *Ecological Applications* (four issues per year). ESA also publishes a bimonthly member newsletter.

A milestone in the Society's development was its 1991 proposal for a **Sustainable Biosphere** Initiative (SBI), which was published in a 1991 issue of *Ecology* as a "call-to-arms for ecologists." Based on research priorities identified in the proposal, ESA chartered the SBI Project Office in the same year to focus on global change, **biodiversity**, and sustainable ecosystems. The SBI marked a commitment by the Society to more actively convey its members' findings to the public and to policy makers, and, as such, included research, education, and environmental decision-making components. The three-pronged SBI proposal grew out of a "period of introspection" during which ESA led its members to examine "the whole realm of ecological activities" in the face of decreasing funds for research, an urgent need to set priorities, and "the need to ameliorate the rapidly deteriorating state of the **environment** and to enhance its capacity to sustain the needs of the world's population."

Since the SBI Project Office was chartered, it has focused on linking the ecological scientific community to other scientists and decision makers through a multi-disciplinary 12-member Steering Committee and five-member staff. For instance, in 1995, the SBI began a series of semi-annual meetings with federal government officials to discuss "overlapping areas of interest and possible collaborative op-

portunities." In addition, SBI has hosted discussions of key ecological topics, such as a symposium on " The Effects of Fishing Activities on Benthic Habitats" that SBI and the American Fisheries Society, the Ecological Society of America, the **National Oceanic and Atmospheric Administration**, and the US **Geological Survey** organized in 2002 and another SBI-hosted discussion on "Ecosystem Simplification: Why a Patchwork Quilt is More Valuable than a Burlap Sack" at the ESA's 2002 Annual Meeting.

In 1993 ESA chartered a Special Committee on the Scientific Basis of **Ecosystem Management** to establish the scientific grounds for discussing the increasingly prominent ecosystem approach to addressing land and natural resource management problems. The committee published its findings in the August 1996 issue of *Ecological Applications*. Articles discussed the emerging consensus on essential elements of ecosystem management, including its "holistic" nature—incorporating the biological and physical elements of an ecosystem and their interrelationships—and the concept of "sustainability" as the "essential element and precondition" of ecosystem management.

ESA's headquarters in Washington, D.C., consistent with the SBI's goal of broader public education, includes a Public Affairs Office. Its Publications Office is in Ithaca, New York.

Ecological economics

Although **ecology** and economics share the common root "eco-" (from Greek *Oikos* or household), these disciplines have tended to be at odds with each other in recent years over issues such as the feasibility of continued economic growth and the value of **natural resources** and environmental services.

Economics deals with resource allocation or trade-offs between competing wants and needs. Economists ask, "what shall we produce, for whom, or for what purpose?" Furthermore, they ask, "when and in what manner should we produce these goods and services?" In mainstream, neoclassical economics, these questions are usually limited to human concerns: what will it cost to obtain the things we desire and what benefits will we derive from them?

According to classical economists, the costs of goods and services are determined by the interaction of supply and demand in the marketplace. If the supply of a particular commodity or service is high but the demand is low, the price will be low. If the commodity is scarce but everyone wants it, the price will be high. But high prices also encourage invention of new technology and substitutes that can satisfy the same demands. The cyclic relationship of scarce resources and development of new technology or new materials, in this view, allows for unlimited growth. And continued economic growth is seen as the best, perhaps the only, solution to poverty and **environmental degradation**.

Ecologists, however, view the world differently than economists. From their studies of the interactions between organisms and their **environment**, ecologists see our world as a dynamic, but finite system that can support only a limited number of humans with their demands for goods and services. Many ecological processes and the nonrenewable natural resources on which our economy is based have no readily available substitutes. Further, much of the natural world is being degraded or depleted at unsustainable rates. Ecologists criticize the narrow focus of conventional economics and its faith in unceasing growth, market valuation, and endless substitutability. Ecologists warn that unless we change our patterns of production and consumption to ways that protect natural resources and ecological systems, we will soon be in deep trouble.

Ecological economics

Ecological or **environmental economics** is a relatively new field that introduces ecological understanding into our economic discourse. It takes a transdisciplinary, holistic, contextual, value-sensitive approach to economic planning and resource allocation. This view recognizes our dependence on the natural world and the irreplaceable life-support services it renders. Rather than express values solely in market prices, ecological economics pays attention to intangible values, nonmarketed resources, and the needs and rights of **future generations** and other **species**. Issues of equitable distribution of access to resources and the goods and services they provide need to be solved, in this perspective, by means other than incessant growth.

Where neoclassical economics sees our environment as simply a supply of materials, services, and waste sinks, ecological economics regards human activities as embedded in a global system that places limits on what we can and cannot do. Uncertainty and dynamic change are inherent characteristics of this complex natural system. Damage caused by human activities may trigger sudden and irreversible changes. The precautionary principle suggests that we

should leave a margin for error in our use of resources and plan for **adaptive management** policies.

Natural capital

Conventional economists see wealth generated by human capital (human knowledge, experience, and enterprise) working with manufactured capital (buildings, machines, and infrastructure) to transform raw materials into useful goods and services. In this view, economic growth and efficiency are best accomplished, by increasing the throughput of raw materials extracted from **nature**. Until they are transformed by human activities, natural resources are regarded as having little value. In contrast, ecological economists see natural resources as a form of capital equally important with human-made capital. In addition to raw materials such as minerals, fuels, fresh water, food, and fibers, nature provides valuable services on which we depend. Natural systems assimilate our wastes and regulate the earth's energy balance, global **climate**, material **recycling**, the chemical composition of the **atmosphere** and oceans, and the maintenance of **biodiversity**. Nature also provides aesthetic, spiritual, cultural, scientific and educational opportunities that are rarely given a monetary value but are, nevertheless, of great significance to many of us.

Ecological economists argue that the value of natural capital should be taken into account rather than treated as a set of unimportant externalities. Our goal, in this view, should be to increase our efficiency in natural resource use and to reduce its throughput. Harvest rates for renewable resources (those like organisms that regrow or those like fresh water that are replenished by natural processes) should not exceed regeneration rates. Waste emissions should not exceed the ability of nature to assimilate or recycle those wastes. **Nonrenewable resources** (such as minerals) may be exploited by humans, but only at rates equal to the creation of renewable substitutes.

Accounting for natural capital

Where neoclassical economics seeks to maximize present value of resources, ecological economics calls for recognition of the real value of those resources in calculating economic progress. A market economist, for example, once argued that the most rational management policy for **whales** was to harvest all the remaining ones immediately and to invest the proceeds in some profitable business. Whales reproduce too slowly, he claimed, and are too dispersed to make much money in the long run by allowing them to remain wild. Ecologists reject this limited view of whales as only economic units of production. They see many other values in these wild, beautiful, sentient creatures. Furthermore whales may play important roles in marine ecology that we don't yet fully understand.

Ecologists are similarly critical of Gross National Product (GNP) as a measure of national progress or well-being. GNP measures only the monetary value of goods and services produced in a national economy. It doesn't attempt to distinguish between economic activities that are beneficial or harmful. People who develop **cancer** from smoking, for instance, contribute to the GNP by running up large hospital bills. The pain and suffering they experience doesn't appear on the balance sheets. When calculating GNP in conventional economics, a subtraction is made, for capital depreciation in the form of wear and tear on machines, vehicles, and buildings used in production, but no account is made for natural resources used up or ecosystems damaged by that same economic activity.

Robert Repeto of the **World Resources Institute** estimates that **soil erosion** in Indonesia reduces the value of crop production about 40% per year. If natural capital were taken into account, total Indonesian GNP would be reduced by at least 20% annually. Similarly, Costa Rica experienced impressive increases in timber, beef, and banana production between 1970 and 1990. But decreased natural capital during this period represented by soil erosion, forest destruction, biodiversity losses, and accelerated water **runoff** add up to at least $4 billion, or about 25%, of annual GNP. Ecological economists call for a new System of National Accounts that recognizes the contribution of natural capital to economic activity.

Valuation of natural capital

Ecological economics requires new tools and new approaches to represent nature in GNP. Some categories in which natural capital might fit include:

- use values: the price we pay to use or consume a resource
- option value: preserving options for the future
- existence value: those things we like to know still exist even though we may never use or even see them
- aesthetic value: things we appreciate for their beauty
- cultural value: things important for cultural identity
- scientific and educational value: information or experience-rich aspects of nature.

How can we measure this value of natural resources and ecological services not represented in market systems? Ecological economists often have to resort to "shadow pricing" or other indirect valuation methods for natural resources. For instance, what is the worth of a day of canoeing on a **wild river**? We might measure opportunity costs such as how much we pay to get to the river or to rent a canoe. The direct out-of-pocket costs might represent only a small portion, however, of what it is really worth to participants. Another approach is contingent valuation in which potential resource users are asked, "how much would you be willing to pay for this experience?" or "what price would you be willing to accept to sell your access or forego this opportunity?" These approaches are controversial because people

may report what they think they ought to pay rather than what they would really pay for these activities.

Carrying capacity and sustainable ddevelopment

Carrying capacity is the maximum number of organisms of a particular species that a given area can sustainably support. Where neoclassical economists believe that technology can overcome any obstacle and that human ingenuity frees us from any constraints on population or economic growth, ecological economists argue that nature places limits on us just as it does on any other species.

One of the ultimate limits we face is energy. Because of the limits of the second law of thermodynamics, whenever work is done, some energy is converted to a lower quality, less useful form and ultimately is emitted as waste heat. This means that we require a constant input of external energy. Many fossil fuel supplies are nearing exhaustion, and continued use of these sources by current technology carries untenable environmental costs. Vast amounts of **solar energy** reach the earth, and this solar energy already drives the generation of all renewable resources and ecological services. By some calculations, humans now control or directly consume about 40% of all the solar energy reaching the earth. How much more can we monopolize for our own purposes without seriously jeopardizing the integrity of natural systems for which there is no substitute? And even if we had an infinite supply of clean, **renewable energy**, how much heat can we get rid of without harming our environment?

Ecological economics urges us to restrain growth of both human populations and the production of goods and services in order to conserve natural resources and to protect remaining natural areas and biodiversity. This does not necessarily mean that the billion people in the world who live in absolute poverty and cannot, on their own, meet the basic needs for food, shelter, clothing, education, and medical care are condemned to remain in that state. Ecological economics calls for more efficient use of resources and more equitable distribution of the benefits among those now living as well as between current generations and future ones.

A mechanism for attaining this goal is **sustainable development**, that is, a real improvement in the overall welfare of all people on a long-term basis. In the words of the World Commission on Economy and Development, sustainable development means "meeting the needs of the present without compromising the ability of future generations to meet their own needs." This requires increased reliance on renewable resources in harmony with ecological systems in ways that do not deplete or degrade natural capital. It doesn't necessarily mean that all growth must cease. There are many human attributes such as knowledge, kindness, compassion, cooperation, and creativity that can expand infinitely without damaging our environment. While ecological economics offers a sensible framework for approaches to resource use that can be in harmony with ecological systems over the long term, it remains to be seen whether we will be wise enough to adopt this framework before it is too late.

Ecological succession

see **Succession**

Ecology

The word ecology was coined in 1870 by the German zoologist Ernst Haeckel from the Greek words *oikos* (house) and *logos* (logic or knowledge) to describe the scientific study of the relationships among organisms and their **environment**. Biologists began referring to themselves as ecologists at the end of the nineteenth century and shortly thereafter the first ecological societies and journals appeared. Since that time ecology has become a major branch of biological science. The contextual, historical understanding of organisms as well as the systems basis of ecology set it apart from the reductionist, experimental approach prevalent in many other areas of science.

This broad ecological view is gaining significance today as modern resource-intensive lifestyles consume much of nature's supplies. Although intuitive ecology has always been a part of some cultures, current environmental crises make a systematic, scientific understanding of ecological principles especially important.

For many ecologists the basic structural units of ecological organization are **species** and populations. A biological species consists of all the organisms potentially able to interbreed under natural conditions and to produce fertile offspring. A population consists of all the members of a single species occupying a common geographical area at the same time. An ecological community is composed of a number of populations that live and interact in a specific region.

This population-community view of ecology is grounded in natural history—the study of where and how organisms live—and the Darwinian theory of natural selection and **evolution**. Proponents of this approach generally view ecological systems primarily as networks of interacting organisms. Abiotic forces such as weather, soils, and **topography** are often regarded as external factors that influence but are apart from the central living core of the system.

In the past three decades the emphasis on species, populations, and communities in ecology has been replaced by a more quantitative, thermodynamic analysis of the processes through which energy flows and the cycling of nutrients and **toxins** are carried out in ecosystems. This process-functional approach is concerned more with the **ecosystem** as a whole than the particular species or populations that make it up. In this perspective, both the living organisms and the abiotic physical components of the environment are equal members of the system.

The feeding relationships among different species in a community are a key to understanding ecosystem function. Who eats whom, where, how, and when determine how energy and materials move through the system. They also influence natural selection, evolution, and species **adaptation** to a particular set of environmental conditions. Ecosystems are open systems, insofar as energy and materials flow through them. Nutrients, however, are often recycled extremely efficiently so that the annual losses to sediments or through surface water **runoff** are relatively small in many mature ecosystems. In undisturbed tropical rain forests, for instance, nearly 100% of leaves and **detritus** are decomposed and recycled within a few days after they fall to the forest floor.

Because of thermodynamic losses every time energy is exchanged between organisms or converted from one form to another, an external energy source is an indispensable component of every ecological system. Green plants capture **solar energy** through **photosynthesis** and convert it into energy-rich organic compounds that are the basis for all other life in the community. This energy capture is referred to as "primary productivity." These green plants form the first trophic (or feeding) level of most communities.

Herbivores (animals that eat plants) make up the next **trophic level**, while carnivores (animals that eat other animals) add to the complexity and diversity of the community. **Detritivores** (such as beetles and earthworms) and **decomposers** (generally bacteria and **fungi**) convert dead organisms or waste products to inorganic **chemicals**. The **nutrient recycling** they perform is essential to the continuation of life. Together, all these interacting organisms form a **food chain/web** through which energy flows and nutrients and toxins are recycled. Due to intrinsic inefficiencies in transferring material and energy between organisms, the energy content in successive trophic levels is usually represented as a pyramid in which primary producers form the base and the top consumers occupy the apex.

This introduces the problem of persistent contaminants in the food chain. Because they tend not to be broken and metabolized in each step in the food chain in the way that other compounds are, persistent contaminants such as pesticides and **heavy metals** tend to accumulate in top carnivores, often reaching toxic levels many times higher than original environmental concentrations. This **biomagnification** is an important issue in **pollution control** policies. In many lakes and rivers, for instance, game fish have accumulated dangerously high levels of **mercury** and **chlorinated hydrocarbons** that present a health threat to humans and other fish-eating species.

Diversity, in ecological terms, is a measure of the number of different species in a community, while abundance is the total number of individuals. Tropical rain forests, although they occupy only about five% of the earth's land area, are thought to contain somewhere around half of all terrestrial plant and animals species, while coral reefs and estuaries are generally the most productive and diverse aquatic communities. Community complexity refers to the number of species at each trophic level as well as the total number of trophic levels and ecological niches in a community.

Structure describes the patterns of organization, both spatial and functional, in a community. In a **tropical rain forest**, for instance, distinctly different groups of organisms live on the surface, at mid-levels in the trees, and in the canopy, giving the forest vertical structure. A patchy mosaic of tree species, each of which may have a unique community of associated animals and smaller plants living in its branches, gives the forest horizontal structure as well.

For every physical factor in the environment there are both maximum and minimum tolerable limits beyond which a given species cannot survive. The factor closest to the tolerance limit for a particular species at a particular time is the critical factor that will determine the abundance and distribution of that species in that ecosystem. Natural selection is the process by which environmental pressures—including biotic factors such as predation, **competition**, and disease, as well as physical factors such as temperature, moisture, **soil** type, and space—affect survival and reproduction of organisms. Over a very long time, given a large enough number of organisms, natural selection works on the randomly occurring variation in a population to allow evolution of species and adaptation of the population to a particular set of environmental conditions.

Habitat describes the place or set of environmental conditions in which an organism lives; **niche** describes the role an organism plays. A yard and garden, for instance, may

provide habitat for a family of cottontail rabbits. Their niche is being primary consumers (eating vegetables and herbs).

Organisms interact within communities in many ways. **Symbiosis** is the intimate living together of two species; **commensalism** describes a relationship in which one species benefits while the other is neither helped nor harmed. **Lichens**, the thin crusty plants often seen on exposed rocks, are an obligate symbiotic association of a fungus and an alga. Neither can survive without the other. Some orchids and bromeliads (air plants), on the other hand, live commensally on the branches of tropical trees. The orchid benefits by having a place to live but the tree is neither helped nor hurt by the presence of the orchid.

Predation—feeding on another organism—can involve pathogens, **parasites**, and herbivores as well as carnivorous predators. Competition is another kind of antagonistic relationship in which organisms vie for space, food, or other resources. Predation, competition, and natural selection often lead to niche specialization and resource partitioning that reduce competition between species. The principle of **competitive exclusion** states that no two species will remain in direct competition for very long in the same habitat because natural selection and adaptation will cause organisms to specialize in when, where, or how they live to minimize conflict over resources. This can contribute to the evolution of a given species into new forms over time.

It is also possible, on the other hand, for species to co- evolve, meaning that each changes gradually in response to the other to form an intimate and often highly dependent relationship either as predator and prey or for mutual aid. Because individuals of a particular species may be widely dispersed in tropical forests, many plants have become dependent on insects, birds, or mammals to carry pollen from one flower to another. Some amazing examples of **coevolution** and mutual dependence have resulted.

Ecological **succession**, the process of ecosystem development, describes the changes through which whole communities progress as different species colonize an area and change its environment. A typical successional series starts with pioneer species such as grasses or fireweed that colonize bare ground after a disturbance. Organic material from these pioneers helps build soil and hold moisture, allowing shrubs and then tree seedlings to become established. Gradual changes in shade, temperature, nutrient availability, wind protection, and living space favor different animal communities as one type of plant replaces its predecessors. Primary succession starts with a previously unoccupied site. Secondary succession occurs on a site that has been disturbed by external forces such as fires, storms, or humans. In many cases, succession proceeds until a mature "climax" community is established. Introduction of new species by natural processes, such as opening of a land bridge, or by human intervention can upset the natural relationships in a community and cause catastrophic changes for indigenous species.

Biomes consist of broad regional groups of related communities. Their distribution is determined primarily by **climate**, topography, and soils. Often similar niches are occupied by different but similar species (called ecological equivalents) in geographically separated biomes. Some of the major biomes of the world are deserts, **grasslands**, **wetlands**, forests of various types, and **tundra**.

The relationship between diversity and **stability** in ecosystems is a controversial topic in ecology. F. E. Clements, an early biogeographer, championed the concept of climax communities: stable, predictable associations towards which ecological systems tend to progress if allowed to follow natural tendencies. Deciduous, broad-leaved forests are climax communities in moist, temperate regions of the eastern United States according to Clements, while grasslands are characteristic of the dryer western plains. In this view, **homeostasis** (a dynamic steady-state equilibrium), complexity, and stability are endpoints in ecological succession. Ecological processes, if allowed to operate without external interference, tend to create a natural balance between organisms and their environment.

H. A. Gleason, another pioneer biogeographer and contemporary of Clements, argued that ecological systems are much more dynamic and variable than the climax theory proposes. Gleason saw communities as temporary or even accidental combinations of continually changing biota rather than predictable associations. Ecosystems may or may not be stable, balanced, and efficient; change, in this view, is thought to be more characteristic than constancy. Diversity may or may not be associated with stability. Some communities such as salt marshes that have only a few plant species may be highly resilient and stable while species-rich communities such as coral reefs may be highly sensitive to disturbance.

Although many ecologists now tend to agree with the process-functional view of Gleason rather than the population-community view of Clements, some retain a belief in the **balance of nature** and the tendency for undisturbed ecosystems to reach an ideal state if left undisturbed. The efficacy and ethics of human intervention in natural systems may be interpreted very differently in these divergent understandings of ecology. Those who see stability and constancy in **nature** often call for policies that attempt to maintain historic conditions and associations. Those who see greater variability and individuality in communities may favor more activist management and be willing to accept change as inevitable.

In spite of some uncertainty, however, about how to explain ecological processes and the communities they create, we have learned a great deal about the world around us

through scientific ecological studies in the past century. This important field of study remains a crucial component in our ability to manage resources sustainably and to avoid or repair environmental damage caused by human actions.

EcoNet

EcoNet is a computer network that focuses on environmental topics and, through the Institute for Global Communications, has links to the international community. Several thousand organizations and individuals have accounts on the network. EcoNet's electronic conferences contain press releases, reports, and electronic discussions on hundreds of topics, ranging from clean air to pesticides. Subscribers can also send e-mail to other users throughout the country and around the world. EcoNet is a branch of ICG Internet, as are PeacNet, WomensNet, and AntiRacismNet.

Economic growth and the environment

The issue of economic growth and the **environment** essentially concerns the kinds of pressures that economic growth, at the national and international level, places on the environment over time. The relationship between **ecology** and the economy has become increasingly significant as humans gradually understand the impact that economic decisions have on the sustainability and quality of the planet.

Economic growth is commonly defined as increases in total output from new resources or better use of existing resources; it is measured by increased real incomes per capita. All economic growth involves transforming the natural world, and it can effect environmental quality in one of three ways. Environmental quality can increase with growth. Increased incomes, for example, provide the resources for public services such as **sanitation** and rural electricity. With these services widely available, individuals need to worry less about day-to-day survival and can devote more resources to **conservation**. Second, environmental quality can initially worsen but then improve as the growth rate rises. In the cases of **air pollution**, **water pollution**, and **deforestation** and encroachment there is little incentive for any individual to invest in maintaining the quality of the environment. These problems can only improve when countries deliberately introduce long-range policies to ensure that additional resources are devoted to dealing with them. Third, environmental quality can decrease when the rate of growth increases. In the cases of emissions generated by the disposal of **municipal solid waste**, for example, abatement is relatively expensive and the costs associated with the emissions and wastes are not perceived as high because they are often borne by someone else.

The **World Bank** estimated that, under present productivity trends and given projected population increases, the output of developing countries would be about five times higher by the year 2030 than it is today. The output of industrial countries would rise more slowly, but it would still triple over the same period. If environmental **pollution** were to rise at the same pace, severe environmental hardships would occur. Tens of millions of people would become sick or die from environmental causes, and the planet would be significantly and irreparably harmed.

Yet economic growth and sound environmental management are not incompatible. In fact, many now believe that they require each other. Economic growth will be undermined without adequate environmental safeguards, and environmental protection will fail without economic growth.

The earth's **natural resources** place limits on economic growth. These limits vary with the extent of resource substitution, technical progress, and structural changes. For example, in the late 1960s many feared that the world's supply of useful metals would run out. Yet, today, there is a glut of useful metals and prices have fallen dramatically. The demand for other natural resources such as water, however, often exceeds supply. In **arid** regions such as the Middle

East and in non-arid regions such as northern China, aquifers have been depleted and rivers so extensively drained that not only **irrigation** and agriculture are threatened but the local ecosystems.

Some resources such as water, forests, and clean air are under attack, while others such as metals, minerals, and energy are not threatened. This is because the **scarcity** of metals and similar resources is reflected in market prices. Here, the forces of resource substitution, technical progress, and structural change have a strong influence. But resources such as water are characterized by open access, and there are therefore no incentives to conserve. Many believe that effective policies designed to sustain the environment are most necessary because society must be made to take account of the value of natural resources and governments must create incentives to protect the environment. Economic and political institutions have failed to provide these necessary incentives for four separate yet interrelated reasons: 1) short time horizons; 2) failures in property rights; 3) concentration of economic and political power; and 4) immeasurability and institutional uncertainty.

Although economists and environmentalists disagree on the definition of sustainability, the essence of the idea is that current decisions should not impair the prospects for maintaining or improving future living standards. The economic systems of the world should be managed so that societies live off the dividends of the natural resources, always maintaining and improving the asset base.

Promoting growth, alleviating poverty, and protecting the environment may be mutually supportive objectives in the long run, but they are not always compatible in the short run. Poverty is a major cause of **environmental degradation**, and economic growth is thus necessary to improve the environment. Yet, ill-managed economic growth can also destroy the environment and further jeopardize the lives of the poor. In many poor but still forested countries, timber is a good short-run source of foreign exchange. When demand for Indonesia's traditional commodity export—petroleum—fell and its foreign exchange income slowed, Indonesia began depleting its hardwood forests at non-sustainable rates in order to earn export income.

In developed countries, it is competition that can shorten time horizons. Competitive forces in agricultural markets, for example, induce farmers to take short-term perspectives for financial survival. Farmers must maintain cash flow to satisfy bankers and make a sufficient return on their land investment. They therefore adopt high-yield crops, **monoculture** farming, increased **fertilizer** and **pesticide** use, salinizing irrigation methods, and more intensive tillage practices which cause **erosion**.

"The Tragedy of the Commons" is the classic example of property rights failure. When access to a grazing area, or commons is unlimited, each herdsman knows that grass not eaten today will not be there tomorrow. As a rational economic being, each herdsman seeks to maximize his gain and adds more animals to his herd. No herdsman has an incentive to prevent his livestock from grazing the area. Degradation follows and the loss of a common resource. In a society without clearly defined property rights, those who pursue their own interests ruin the public good.

In Indonesia, political upheaval can void property rights overnight, and so any individual with a concession to harvest trees is motivated to harvest as many and as quickly as possible. The government-granted timber-cutting concession may belong to someone else tomorrow. The same is true of some developed countries. For example, in Louisiana mineral rights revert to the state when **wetlands** become open water and there has been no mineral development on the property. Thus, the cheapest methods of avoiding loss of mineral revenues has been to hurry the development of oil and gas in areas which might revert to open water, thereby, hastening erosion and saltwater intrusion, or putting up levies around the property to maintain it as private property, thus interfering with normal estuarine processes.

Global or transnational problems such as **ozone layer depletion** or **acid rain** produce a similar problem. Countries have little incentive to reduce damage to the global environment unilaterally when doing so will not reduce the damaging behavior of others or when reduced fossil fuel use would leave that country at a competitive disadvantage. International agreements are thus needed to impose order on the world's nations that would be analogous to property rights.

Concentration of wealth within the industrialized countries allows for the exploitation and destruction of ecosystems in **less developed countries** (LDC) through, for example, timber harvests and mineral extraction. The concentration of wealth inside a less developed country skews public policy toward benefiting the wealthy and politically powerful, often at the expense of the **ecosystem** on which the poor depend. Local sustainability is dependent upon the goals of those who have power—goals which may or may not be in line with a healthy, sustainable ecosystem. Furthermore, when an exploiting party has substitute ecosystems available, it can exploit one and then move to the next. Japanese lumber firms harvest one country and then move on to another. Here the benefits of sustainability are low and exploiters have shorter time horizons than local interests. This is also an example of how the high discount rates in developed countries are imposed on the management of developing countries' assets.

Environmental policy-making is always more complicated than merely measuring the effects that a proposed policy on the environment. But because of scientific uncertainty about biophysical and geological relations and a gen-

eral inability to measure a policy's effect on the environment, economic rather than ecological effects are more often relied upon to make policy. Policy-makers and institutions are often unable to grasp the direct and indirect effects of policies on ecological sustainability, nor do they know how their actions will affect other areas not under their control.

Many contemporary economists and environmentalists argue that the value of the environment should nonetheless be factored into the economic policy decision-making process. The goal is not necessarily to put monetary values on **environmental resources**; it is rather to determine how much environmental quality is being given up in the name of economic growth, and how much growth is being given up in the name of the environment. A danger always exists that too much income growth may be given up in the future because of a failure to clarify and minimize tradeoffs and to take advantage of policies that are good for both economic growth and the environment. *See also* Energy policy; Environmental economics; Environmental policy; Environmentally responsible investing; Exponential growth; Sustainable agriculture; Sustainable biosphere; Sustainable development

Ecosophy

A philosophical approach to the **environment** which emphasizes the importance of action and individual beliefs. Often referred to as "ecological wisdom," it is associated with other **environmental ethics**, including **deep ecology** and **bioregionalism**.

Ecosophy originated with the Norwegian philosopher Arne Naess. Naess described a structured form of inquiry he called *ecophilosophy*, which examines **nature** and our relationship to it. He defined it as a discipline, like philosophy itself, which is based on analytical thinking, reasoned argument, and carefully examined assumptions. Naess distinguished ecosophy from ecophilosophy; it is not a discipline in the same sense but what he called a "personal philosophy," which guides our conduct toward the environment. He defined ecosophy as a set of beliefs about nature and other people which varies from one individual to another. Everyone, in other words, has their own ecosophy, and though our personal philosophies may share important elements, they are based on norms and assumptions that are particular to each of us.

Naess proposed his own ecophilosophy as a model for individual ecosophies, emphasizing the **intrinsic value** of nature and the importance of cultural and natural diversity. Other discussions of ecosophy concentrate on similar issues. Many environmental philosophers argue that all life has a value that is independent of human perspectives and human uses, and that it is not to be tampered with except for the sake of survival. Human **population growth** threatens the integrity of other life systems; they argue that our numbers must be reduced substantially and that radical changes in human values and activities are required to integrate humans more harmoniously into the total system. *See also* Zero population growth

Ecosystem

The term ecosystem was coined in 1935 by the Oxford ecologist Arthur Tansley to encompass the interactions among biotic and abiotic components of the **environment** at a given site. It was defined in its presently accepted form by Eugene Odum as follows: "Any unit that includes all of the organisms (i.e, the community) in a given area interacting with the physical environment so that a flow of energy leads to clearly defined trophic structure, biotic diversity, and material cycles (i.e., exchange of materials between living and non-living parts) within the system." Tansley's concept had been expressed earlier in 1913 by the Oxford geographer A. J. Herbertson, who suggested the term "macroorganism" for such a combined biotic and abiotic entity. He was, however, too far in advance of his time and the idea was not taken up by ecologists. On the other hand Tansley's concept—elaborated in terms of the transfer of energy and matter across ecosystem boundaries–was utilized within the next

few years by Evelyn Hutchinson, Raymond Lindeman, and the Odum brothers, Eugene and Howard.

The boundaries of an ecosystem can be somewhat arbitrary, reflecting the interest of a particular ecologist in studying a certain portion of the landscape. However, such a choice may often represent a recognizable landscape unit such as a woodlot, a wetland, a stream or lake, or—in the most logical case—a **watershed** within a sealed geological basin, whose exchanges with the **atmosphere** and outputs via stream flow can be measured quite precisely. Inputs and outputs imply an **open system**, which is true of all but the planetary or global ecosystem, open to **energy flow** but effectively closed in terms of materials except in the case of large-scale asteroid impact.

Ecosystems exhibit a great deal of structure, as may be seen in the vertical partitioning of a forest into tree, shrub, herb, and moss layers, underlain by a series of distinctive **soil** horizons. Horizontal structure is often visible as a mosaic of patches, as in forests with gaps where trees have died and herbs and shrubs now flourish, or in bogs with hummocks and hollows supporting different kinds of plants. Often the horizontal structure is distinctly zoned, for instance around the shallow margin of a lake; and sometimes it is beautifully patterned, as in the vast **peatlands** of North America that reflect a very complicated **hydrology**.

Ecosystems exhibit an interesting functional organization in their processing of energy and matter. Green plants, the primary producers of organic matter, are consumed by herbivores, which in turn are eaten by carnivores that may in turn be the prey of other carnivores. Moreover, all these animals may have **parasites** as another set of consumers. Such sequences of producers and successive consumers constitute a food chain, which is always part of a complicated, inter-linked food web along which energy and materials pass. At each step along the food chain some of the energy is egested or passed through the organisms as feces. Much more is used for metabolic processes and—in the case of animals—for seeking food or escaping predators; such energy is released as heat. As a consequence only a small fraction (often of the order of 10%) of the energy captured at a given step in the food chain is passed along to the next step.

There are two main types of food chains. One is made up of plant producers and animal consumers of living organisms, which constitute a grazing food chain. The other consists of organisms that break down and metabolize dead organic matter, such as earthworms, **fungi**, and bacteria. These constitute the **detritus** food chain. Humans rely chiefly on grazing food chains based on **grasslands**, whereas in a forest it is usual for more than 90% of the energy trapped by **photosynthesis** to pass along the detritus food chain.

Whereas energy flows one way through ecosystems and is dispersed finally to the atmosphere as heat, materials are partially and often largely recycled. For example, **nitrogen** in rain and snow may be taken up from the soil by roots, built into leaf protein that falls with the leaves in autumn, there to be broken down by soil **microbes** to ammonia and nitrate and taken up once again by roots. A given molecule of nitrogen may go through this **nutrient** cycle again and again before finally leaving the system in stream outflow. Other nutrients, and **toxins** such as **lead** and **mercury**, follow the same pathway, each with a different **residence time** in the forest ecosystem.

Mature ecosystems exhibit a substantial degree of **stability**, or dynamic equilibrium, as the endpoint of what is often a rather orderly **succession** of **species** determined by the **nature** of the **habitat**. Sometimes this successional process is a result of the differing life spans of the colonizing species, at other times it comes about because the colonizing species alter the habitat in ways that are more favorable to their competitors, as in an **acid** moss bog that succeeds a circumneutral sedge fen that has in its turn colonized a pond as a floating mat. Equilibrium may sometimes be represented on a large scale by a relatively stable mosaic of small-scale patches in various stages of succession, for instance in fire-dominated pine forests. On the millennial time scale, of course, ecosystems are not stable, changing very gradually owing to immigration and emigration of species and to evolutionary changes in the species themselves.

The structure, function, and development of ecosystems are controlled by a series of partially independent environmental factors: **climate**, soil parent material, **topography**, the plants and animals available to colonize a given site, and disturbances such as fire and windthrow. Each factor is, of course, divisible into a variety of components, as in the case of temperature and precipitation under the general heading of climate.

There are many ways to study ecosystems. Evelyn Hutchinson divided them into two main categories, holistic and meristic. The former treats an ecosystem as a "black box" and examines inputs, storages, and outputs, for example in the construction of a lake's heat budget or a watershed's chemical budget. This is the physicist's or engineer's approach to how ecosystems work. The meristic point of view emphasizes analysis of the different parts of the system and how they fit together in their structure and function, for example the various zones of a wetland or a **soil profile**, or the diverse components of food webs. This is the biologist's approach to how ecosystems work.

Ecosystem studies can also be viewed as a series of elements. The first is, necessarily, a description of the system, its location, boundaries, plant and animal communities, environmental characteristics, etc. Description may be followed by any or all of a series of additional elements, including: 1) a study of how a given ecosystem compares with others

locally, regionally, or globally; 2) how it functions in terms of hydrology, productivity, and biogeochemical cycling of nutrients and toxins; 3) how it has changed over time; and 4) how various environmental factors have controlled its structure, function, and development. Such studies involve empirical observations about relationships within and among ecosystems, experiments to test the causality of such relationships, and model-building to assist in forecasting what may happen in the future.

The ultimate in ecosystem studies is a consideration of the structure, function, and development of the global or planetary ecosystem, with a view to understanding and mitigating the deleterious impacts upon it of current human activities. *See also* Biotic community

Ecosystem health

Ecosystem health is a new concept that ecologists are examining as a tool for use in detecting and monitoring changes in the quality of the **environment**, particularly with regard to ecological conditions.

Ecosystem health (and **ecological integrity**) is an indicator of the well-being and natural condition of ecosystems and their functions. These indicators are influenced by natural changes in environmental conditions, and are related to such factors as **climate** change and disturbances such as **wildfire**, windstorms, and diseases. Increasingly, however, ecosystems are being affected by environmental stressors associated with human activities that cause **pollution** and disturbance, which result in many changes in environmental conditions. Some **species**, communities, and ecological processes benefit from those environmental changes, but others suffer great damages.

The notion of ecosystem health is intended to help distinguish between ecosystem-level changes that represent improvements and those that are considered to be degradations. In the sense meant here, ecosystem-level refers to responses occurring in ecological communities, landscapes, or seascapes. Effects on individual organisms or populations do not represent an ecosystem-level response to changes in environmental conditions.

The notion of health

The notion of ecosystem health is analogous to that of medical health. In the medical sense, health is a term used to refer to the vitality or well-being of individual organisms. Medical health is a composite attribute, because it is characterized by a diversity of inter-related characteristics and conditions. These include blood pressure and chemistry, wounds and injuries, rational mental function and many other relevant variables. Health is, in effect, a summation of all of these characters related to vitality and well-being. In contrast, a diagnosis of unhealthiness would focus on abnormal values for only one or several variables within the diverse congregation of health-related attributes. For example, an individual might be judged as being unhealthy because they had a broken leg, or a high fever, or unusually high blood pressure, or non-normal behavioral traits, even though they are "normal" with regards to all other traits.

To compare human and ecosystem health is, however, imperfect in some important respects. Health is a relative concept. It depends on what we consider "normal" at a particular stage of development. The aches and pains that are considered normal in a human at age 80 would be a serious concern in a 20-year old. It is much more difficult, however, to say what is to be expected in an ecosystem. Ecosystems don't have a prescribed lifespan and generally don't die but rather change into some other form. Because of these problems, some ecologists prefer the notions of ecological or biological integrity rather than ecosystem health.

It should also be pointed out that many ecologists like none of these notions (that is, ecosystem health, ecological integrity, or biological integrity). The reason is that by their very nature, these concepts are imprecise and difficult to define. For these reasons, scientists have had difficulty in agreeing upon the specific variables that should be included when designing composite indicators of health and integrity in ecological contexts.

Ecosystem health

Ecosystem health is a summation of conditions occurring in communities, watersheds, landscapes, or seascapes. Ecosystem health conditions are higher-level components of ecosystems, in contrast with individual organisms and their populations.

Although ecosystem health cannot be defined precisely, ecologists have identified a number of specific components that are important in this concept. These include the following indicators: (1) an ability of the system to resist changes in environmental conditions without displaying a large response (this is also known as **resistance** or tolerance); (2) an ability to recover when the intensity of **environmental**

stress is decreased (this is known as **resilience**); (3) relatively high degrees of **biodiversity**; (4) complexity in the structure and function of the system; (5) the presence of large species and top predators; (6) controlled **nutrient** cycling and a stable or increasing content of **biomass** in the system; and (7) domination of the system by native species and natural communities that can maintain themselves without management by humans. Higher values for any of these specific elements imply a greater degree of ecosystem health, while decreasing or lower values imply changes that reflect a less healthy condition.

Ecologists are also working to develop composite indicators (or multivariate summations) that would integrate the most important attributes of ecosystem health into a single value. Indicators of this type are similar in structure to composite economic indicators such as the Dow-Jones Stock Market Index and the Consumer Price Index. Because they allow complex situations to be presented in a simple and direct fashion, composite indicators are extremely useful for communicating ecosystem health to the broader public.

Ecosystem management

Ecosystem management (EM) is a concept that has germinated within the past 20 years and continues to increase in popularity across the United States and Canada. It is a concept that eludes one concise definition, however, because it embodies different meanings in different contexts and for different people and organizations. This can be witnessed by the multiple variations on its title, e.g., ecosystem-based management or collaborative ecosystem management. The definitions that have been given for EM, though varied, fall into two distinct groups. One group emphasizes long term ecosystem integrity, while the other group emphasizes an intention to address all concerns equally, be they economic, ecological, political or social, by actively engaging and incorporating the multitude of stakeholders (literally, those who "hold a stake" in the issue) into the decision-making process.

One usable though incomplete definition of EM is provided by R. Edward Grumbine: "Ecosystem management integrates scientific knowledge of ecological relationships within a complex sociopolitical and values framework toward the general goal of protecting native ecosystem integrity over the long term." Ultimately, EM is a new way to make decisions about how we humans should live with each other and with the **environment** that supports us. And, it is best defined not only by articulating an ideal description of its contents, as Grumbine has done, but also through a rigorous analysis of actual EM examples.

EM—a new management Style

Between the years 1992 and 1994, each of the four predominant federal land management agencies in the United States the **National Park Service**, the **Bureau of Land Management**, the **Forest Service** and the **Fish and Wildlife Service** implemented EM as their operative management paradigm. Combined, these four agencies combined control 97% of the 650 million federally-owned acres (267 million ha) in the United States, or roughly 30% of the United States' entire land area. EM has become the primary management style for these agencies because of a fact that became unavoidably apparent in the 1980s and 1990s the traditional resource management style does not work. It is largely ineffective in addressing the loss and fragmentation of wild areas, the increasing number of threatened or **endangered species**, and the increased occurrence of environmental disputes. This ineffectiveness has been attributed to the traditional management style's focus on mainly **species** with economic value, its exclusion of the public from the decision-making process, and its reliance on outdated ecological beliefs. This explicit acknowledgment that the traditional management style is inadequate has coalesced within state and federal agencies, academia, and environmental organizations, and has been bolstered by advances in other relevant fields, such as **ecology** and conflict management.

If we break the traditional management style into individual components, we see that each ineffective attribute has a new or altered counterpart in EM. One of the best ways to describe what EM actually entails is to explicate this juxtaposition between traditional and new management styles.

EM, as its name makes clear, concentrates on managing at the scale of an ecosystem. Alternately, traditional resource management has tended to focus only on one or a handful of species, especially those species that have a utilitarian, or more specifically economic, value. For example, the U.S. Forest Service has traditionally managed the national forests so as to produce a sustained yield of timber. This management style is often harmful to species other than timber and can have negative effects on the entire ecosystem. In EM, all significant biotic and abiotic components of the ecosystem, as well as aspects such as economic factors, are, ideally, reviewed and the important ecological

data incorporated into the decision-making process. For example, review of a forest ecosystem may include an analysis of **habitat** for significant song birds, a description of the requirements needed to maintain a healthy black bear (*Ursus americanus*) population, *and* a discussion of acceptable levels of timber production.

A major problem associated with using an ecosystem to define one's management area is that boundaries of jurisdictional authority, or political boundaries, rarely follow ecological ones. This implies that by following political boundaries alone, ecological components may be left out of the management plan one may be forced to manage only part of an ecosystem, that part which is within one's political jurisdiction. For example, the Greater Yellowstone Ecosystem goes far beyond the boundaries of **Yellowstone National Park**. Therefore, a large scale EM project for Yellowstone would require crossing several political boundaries (e.g., **national park** lands and **national forest** lands), which is a difficult task because it entails several political jurisdictions and political entities (e.g., state and federal agencies, and county governments).

EM projects address this obstacle by forming decision teams that include, among others, representatives from all of the relevant jurisdictions. These decision-making bodies can either act as advisory committees without decision-making authority, or they can attempt to become vested with the power to make decisions. This collaborative process involves all of the stakeholders, whether that stakeholder is a **logging** company interested in timber production, or a private citizen concerned with **water quality**. Such collaboration diverges from the traditional resource management method which made most decisions "behind closed doors" asking for and receiving little public input. These agencies traditionally shied away from actively engaging the public because it is easier and faster to make decisions on one's own than to ask for input from many sources, there has often been an antagonistic and distrustful relationship between state and federal agencies and the public, and, there has been little institutional support (i.e., within the structure of the agency itself) encouraging the manager in the field to invite the public into the decision-making process.

EM's more collaborative and inclusive decision-making style ideally fosters a wiser and more effective decision. This happens because as the decision team works toward consensus, personal relationships are established, some trust may form between parties, and, ultimately, people are more likely to support a decision or plan they help create. EM attempts to transcend the traditional antagonistic relationship between agency personnel and the public. Because 70% of the United States is privately owned, many environmental issues arise on private land—land that is partially not affected by federal and state natural resource legislation. EM allows us to deal with these issues on private lands by establishing a dialogue between private and public decision makers. Finally, even though the EM decision-making style takes longer to conduct, time is saved in the end because the decision achieved is more agreeable to all interested parties. Having all parties agree to a particular management plan decreases the number of potential lawsuits which can arise and delay the plan's implementation.

Nonequilibrium ecology and EM

A change in the dominant theories in ecology has encouraged this switch to EM and an ecosystem-level focus.

The idea that environments achieve a climax state of **homeostasis** has been a significant theory in ecology since the early 1900s. This view, now discredited, was most vigorously articulated by Frederic Clements and holds that all ecosystems have a particular end point to which they each progress, and that ecosystems are closed systems. Disturbances such as fires or floods are considered only temporary setbacks on the ecosystem's ultimate progression to a final state. This theory offers a certain level of predictable **stability** the type of stability desired within traditional resource management. For example, if a forest is in its climax state, that condition can be maintained by eliminating disturbances such as forest fires, and a predictable level of harvestable timber can be extracted (hence, this theory contributed to the creation of "Smoky the Bear" and the national policy of stopping forest fires on **public land**).

This teleological view of **nature** has ebbed and waned in importance, but has lost favor especially within the past two decades. Ecologists, among others, have realized that from certain temporal and spatial points of view ecosystems may seem to be in equilibrium, but in the long term all ecosystems are in a state of nonequilibrium. That is, ecosystems always change. They change because their ecological structure and function is often regulated by dynamic external forces such as storms or droughts and because they comprise of varied habitat types which change and affect one another.

This acknowledgment of a changing ecosystem means that predictable stability does not really exist and that an **adaptive management** style is needed to meet the changing requirements of a dynamic ecosystem. EM is adaptive. After an EM decision team has formulated and implemented a management plan, the particular ecosystem is monitored. The team watches significant biotic and abiotic factors are watched to see if and how they are altered by the management practices. For example, if logging produces changes which effect the fish in one of the ecosystem's streams, the decision team could adapt to the new data and decide to relocate the logging.

The ability to adaptively manage is a crucial aspect of EM, one that is not incorporated in traditional resource management. As stated, the traditional management style

emphasizes one or a few species and believes that ecosystems are mostly stable. So, one only needs to view how a particular species fares to determine the necessary management practices little monitoring is conducted and previous management practices are rarely altered. In EM, management practices are constantly reviewed and adjusted as a result of ongoing data gathering and the goals articulated by the decision team.

The future of EM

The future of EM in the United States and Canada looks stable, and other countries such as France are beginning to use EM. There are many impediments, though, to the successful implementation of EM. Institutions, such as the United States' federal land management agencies, are often hesitant to actually change and when they do change it happens very slowly; there are still many legal questions surrounding the legitimacy of implementing EM on federal, state and private lands; and, even though we attempt to review the entire ecosystem in EM examples, we still lack significant understanding of how even the most basic ecosystems operate. Even given these impediments, it looks as if EM will be the primary land management style of the United States and Canada well into the next century.

Ecotage

see **Ecoterrorism; Monkey-wrenching**

Ecoterrorism

In the wake of the terrorist attacks on the World Trade Center in New York City on September 11, 2001, the line between radical environmental protest (sometimes called ecoanarchism) and terrorism became blurred by strong emotions on all sides. Environmentalists in America have long held passionate beliefs about protecting the **environment** and saving threatened **species** from **extinction**, as well as treating animals humanely and protesting destructive business practices. One of the first and greatest environmentalists, **Henry David Thoreau** (1817–1862), wrote about the doctrine of "civil disobedience," or using active protest as a political tool. The author Edward Abbey (1927–1989) became a folk hero among environmentalists when he wrote the novel, *The Monkey Wrench Gang*, in 1975. In that book, a group of militant environmentalists practiced **monkey-wrenching**, or sabotaging machinery in desperate attempts to stop **logging** and mining. Monkey-wrenching, in its destruction of private property, goes beyond civil disobedience and is unlawful. The American public has tended to view monkey-wrenchers as idealistic youth fighting for the environment and has not strongly condemned them for their actions. However, the U.S. government views monkey-wrenching as domestic terrorism, and since September 11, 2001, law enforcement activity concerning environmental groups has been significantly increased.

Ecoanarchism is the philosophy of certain environmental or **conservation** groups that pursue their goals through radical political action. The name reflects both their relation to older anarchist revolutionary groups and their distrust of official organizations. Nuclear issues, social responsibility, **animal rights**, and grass-roots democracy are among the concerns of ecoanarchists. Ecoanarchists tend to view mainstream political and environmental organizations as too passive, and those who maintain them as compromising or corrupt. Ecoanarchists may resort to direct confrontation, direct action, civil disobedience, and guerrilla tactics to fight for survival of wild places. Monkey-wrenchers perform sit-ins in front of bulldozers; they disable machinery in various ways including pouring sand in a bulldozer's gas tank; they ram **whaling** ships; and they spike trees by driving metal bars into them to discourage logging. Ecoanarchists may practice ecotage, which is sabotage for environmental ends, often of machines that alter the landscape. In the early 2000s, radical environmentalists committed arson on 35 sport utility vehicles (SUVs) at a car dealership in Eugene, Oregon, to protest the gas-guzzling vehicles, and set fire to buildings at the University of Washington to protest **genetic engineering**, for example.

Ecoanarchists do not necessarily view the destruction of machinery as out-of-bounds, but the U.S. government views it as terrorism. For instance, **Earth First!**, a radical environmental group whose motto is, "No Compromise in Defense of Mother Earth," takes a stand against violence against humans but does approve of monkey-wrenching. The Federal Bureau of Investigation (FBI) defines terrorism as, "the unlawful use, or threatened use, of violence by a group or individual ... committed against persons or property to intimidate or coerce a government, the civilian population or any segment thereof, in furtherance of political or social

objectives." The FBI reports that an estimated 600 criminal acts of ecoterrorism have occurred in the United States since 1996, with damages estimated at $43 million. Two groups associated with these acts of sabotage are the militant **Earth Liberation Front** (ELF) and Animal Liberation Front (ALF) groups. In 1998, ELF took credit for arson at Vail Ski Resort, which resulted in damages of $12 million. The act was a protest over the resort's expansion on mountain ecosystems.

Most environmental groups are more peaceful and have voiced concern over radical environmentalists, as well as over law enforcement officials who view all environmental protesters as terrorists. For instance, **Greenpeace** activists have been known to steer boats in the path of whaling ships and throw paint on nuclear vessels as protest, and have been jailed for doing so, although no people were targeted or injured. **People for the Ethical Treatment of Animals** (PETA) members have thrown pies in the faces of business executives whom they found guilty of inhumane treatment of animals, considering the act a form of civil disobedience and not violence.

The issues of ecoterrorism and ecoanarchism become more heated as **environmental degradation** worsens. Environmentalists become more desperate to protect rapidly disappearing endangered areas or species, while industry continually seeks new resources to replace those being used up. Thrown in the middle are law enforcement officials, who must protect against violence and destruction of property, and also uphold citizens' basic rights to protest.

The most famous ecoterrorist has been Theodore Kaczynski, also known as the Unabomber, who was convicted of murder in the mail-bombing of the president of the California Forestry Association. On the other end of the spectrum of environmental protest is Julia Butterfly Hill, whom ecoterrorists and ecoanarchists would do well to emulate. Hill is an activist who lived in a California redwood tree for two years to prevent it from being cut down by the Pacific Lumber Company. Hill practiced a nonviolent form of civil disobedience, and endured what she perceived as violent actions from loggers and timber company actions. Her peaceful protest brought national attention to the issue of logging in ancient growth forests, and a compromise was eventually reached between environmentalists and the timber company. Unfortunately, the tree in which Hill sat, which she named Luna, was damaged by angry loggers.

Ecotone

The boundary between adjacent ecosystems is known as an ecotone. For example, the intermediary zone between a grassland and a forest constitutes an ecotone that has characteristics of both ecosystems. The transition between the two ecosystems may be abrupt or, more commonly, gradual. Because of the overlap between ecosystems, an ecotone usually contains a larger variety of **species** than is to be found in either of the separate ecosystems and often includes species unique to the ecotone. This effect is known as the edge effect. Ecotones may be stable or variable. Over a period of time, for example, a forest may invade a grassland. Changes in precipitation are an important factor in the movement of ecotones.

Ecotourism

Ecotourism is ecology-based tourism, focused primarily on natural or cultural resources such as scenic areas, coral reefs, caves, fossil sites, archeological or historical sites, and **wildlife**, particularly rare and **endangered species**.

The successful marketing of ecotourism depends on destinations which have **biodiversity**, unique geologic features, and interesting cultural histories, as well as an adequate infrastructure. In the United States national parks are perhaps the most popular destinations for ecotourism, particularly **Yellowstone National Park**, the Grand Canyon, the **Great Smoky Mountains** and **Yosemite National Park**. In 1999, there were 300 million recreational visits to the national parks. Some of the leading ecotourist destinations outside the United States include the Galapagos Islands in Ecuador, the wildlife parks of Kenya, Tanzania, and South Africa, the mountains of Nepal, and the national parks and forest reserves of Costa Rica.

Tourism is the second largest industry in the world, producing over $195 billion in domestic and international receipts and accounting for more than 7% of the world's trade in goods and services. There were 693 million international tourists in 2001, creating 74 million tourism jobs. Adventure

tourism, which includes ecotourism, accounts for 10% of this market. In developing countries tourism can comprises as much as one-third of trade in goods and services, and much of this is ecotourism. Wildlife-based tourism in Kenya, for example, generates $350 million annually.

Ecotourism is not a new phenomena. In the late 1800s railroads and steamship companies were instrumental in the establishment of the first national parks in the United States, recognizing even then the demand for experiences in **nature** and profiting from transporting tourists to destinations such as Yellowstone and Yosemite. However, ecotourism has recently taken on increased significance worldwide.

There has been a tremendous increase in demand for such experiences, with adventure tourism increasing at a rate of 30% annually. But there is another reason for the increased significance of ecotourism. It is a key strategy in efforts to protect cultural and **natural resources**, especially in developing countries, because resource-based tourism provides an economic incentive to protect resources. For example, rather than converting tropical rain forests to farms which may be short-lived, income can be earned by providing goods and services to tourists visiting the rain forests.

Although ecotourism has the potential to produce a viable economic alternative to exploitation of the **environment**, it can also threaten it. **Water pollution**, litter, disruption of wildlife, trampling of vegetation, and mistreatment of local people are some of the negative impacts of poorly planned and operated ecotourism. To distinguish themselves from destructive tour companies, many reputable tour organizations have adopted environmental codes of ethics which explicitly state policies for avoiding or minimizing environmental impacts. In planning destinations and operating tours, successful firms are also sensitive to the needs and desires of the local people, for without native support efforts in ecotourism often fail.

Ecotourism can provide rewarding experiences and produce economic benefits that encourage **conservation**. The challenge upon which the future of ecotourism depends is the ability to carry out tours which the clients find rewarding, without degrading the natural or cultural resources upon which it is based. *See also* Earthwatch; National Park Service

Ecotoxicology

Ecotoxicology is a field of science that studies the effects of toxic substances on ecosystems. It analyzes environmental damage from **pollution** and predicts the consequences of proposed human actions in both the short and long term. With more than 100,000 **chemicals** in commercial use and thousands more being introduced each year, the scale of the task is daunting. Ecotoxicologists have a variety of methods with which they measure the impact of harmful substances on people, plants, and animals. Toxicity tests measure the response of biological systems to a substance to determine if it is toxic. A test could study, for example, how well fish live, grow, and reproduce in various concentrations of industrial **effluent**. Another could evaluate the point at which metal contaminants in **soil** damage plants' ability to convert sunlight into food. Still another could measure how various concentrations of pesticides in agricultural **runoff** affect **sediment** and **nutrient absorption** in **wetlands**. Analyses of chemical fate (i.e., where a pollutant goes once it is released into the **environment**) can be combined with toxicity-test information to predict environmental response to pollution. Because toxicity is the interaction between a living system and a substance, only living plants, animals,

and systems can be used in these experiments. There is no other way to measure toxicity.

Another tool used in ecotoxicology is the field survey. It describes ecological conditions in both healthy and damaged natural systems, including pollution levels. Surveys often focus on the number and variety of plants and animals supported by the **ecosystem**, but they can also characterize other valued attributes such as crop yield, **commercial fishing**, timber harvest, or aesthetics. Information from a number of field surveys can be combined for an overview of the relationship between pollution levels and the ecological condition.

A logical question might be: why not merely measure the concentration of a **toxic substance** and predict what will happen from that? The answer is because chemical analysis alone cannot predict environmental consequences in most cases. Unfortunately, interactions between toxicants and the components of ecosystems are not clear; in addition, ecotoxicologists have not yet developed simulation models that would allow them to make predictions based on chemical concentration alone. For example:

- An ecosystem's response to toxic materials is greatly influenced by environmental conditions. The concentration of zinc that will kill bluegill sunfish in Virginia's soft waters will not kill them in the much harder waters of Texas. Most of the relationships between environmental conditions and toxicity have not been established.
- Most pollution is a complex mixture of chemicals, not just a single substance. In addition, some chemicals are more harmful when combined with other toxicants.
- Some chemicals are toxic at concentrations and levels too small to be measured.
- An organism's response to toxic materials can be influenced by other organisms in the community. For example, a fish exposed to pollution may be unable to escape from its predators.

Ecotoxicologists use all three kinds of information: field surveys, chemical analyses, and toxicity tests. Field surveys prove that some important characteristic of the ecosystem has been damaged, chemical measurements confirm the presence of a toxicant, and toxicity tests link a particular toxicant to a particular type of damage.

The scope of environmental protection has broadened considerably over the years, and the types of ecotoxicological information required have also changed. Toxicity testing began as an interest in the effects of various substances on human health. Gradually this concern extended to the other organisms that were most obviously important to humans—domestic animals and crop plants—and finally spread to other organisms that are less apparent or universal in their importance. Hunters are interested in deer, fishers in fish, bird watchers in eagles or pelicans, and beachcombers in loggerhead turtles. Keeping these organisms healthy requires studying the effects of pollution on them. In addition, the toxicant must not eliminate or taint the plants and/or animals upon which they feed nor can it destroy their **habitat**. Indirect effects of toxicants, which can also be devastating, are difficult to predict. A chemical that is not toxic to an organism, but instead destroys the grasses in which it lays eggs or hides from predators, will be indirectly responsible for the death of that organism. Protecting all the **species** that people value, along with their food and habitat, is a small step toward universal protection. An ambitious goal is to prevent the loss of any existing species, regardless of its appeal or known value to human society.

Because each one of the millions of species on this planet cannot be tested before a chemical is used, ecotoxicologists tested a few "representative" species to characterize toxicity. If a pollutant could be found in rivers, testing might be done on an alga, an insect that eats algae, a fish that eats insects, and a fish that eats fish. Other representative species are chosen by their habitat: on the bottom of rivers, midstream, or in the soil. Regardless of the sampling scheme, however, thousands of organisms that will be affected by a pollutant will not be tested.

Some prediction must be made about their response, nonetheless. Statistical techniques can predict the response of organisms in general from information on a few randomly selected organisms. Another approach tests the well-being of higher levels of biological organization. Since natural communities and ecosystems are composed of a large number of interacting species, the response of the whole reflects the responses of its many constituents. The health of a large and complex ecosystem cannot be measured in the same way as the health of a single species, however. Different attributes are important. For example, examining a single species like cattle or trout might require measuring **respiration**, reproduction, behavior, growth, or tissue damage. The condition of an ecosystem, on the other hand, might be determined by measuring production, nutrient spiralling, or colonization. Since people depend on ecosystems for food production, waste processing, and **biodiversity**, keeping them healthy is important.

Ecotype

A recognizable geographic variety, population, or ecological race of a widespread **species** that is equivalent to a taxonomic subspecies. Typically, ecotypes are restricted to one **habitat** and are recognized by distinctive characteristics resulting from adaptations to local selective pressures and isolation. For example, a population or ecotype of species found at the foot of a mountain may differ in size, color, or physiology from a different ecotype living at higher altitudes, thus reflecting a sharp change in local selective pressures. Members of an ecotype are capable of interbreeding with other ecotypes within the same species without loss of fertility or vigor.

Ectopistes migratorius

see **Passenger pigeon**

Edaphic

Refers to the concept that soils have influence on living things, particularly plants. For example, soils with a low **pH** will more likely have plants growing on them that are adapted to this level of **soil** acidity. Animals living in the area will most likely eat these acid-loving plants. The more extreme a soil characteristic, the fewer kinds of plants and animals are able to adapt to the soil **environment**.

Edaphology

The ecological study of **soil**, including its role, value, and management as a medium for plant growth and as a **habitat** for animals. This branch of soil science covers physical, chemical, and biological properties, including soil fertility, acidity, water relations, gas and energy exchanges, microbial **ecology**, and organic decay.

Eelgrass

Eelgrass is the common name for a genus of perennial grass-like flowering plants referred to as *Zostera*. *Zostera* is from the Greek word *zoster* meaning belt, which describes the dark green, long, narrow, ribbon shape of the leaves that range in size from 20 to 50 cm in length, but can grow up to 2 m. Eelgrass grows under water in estuaries and in shallow coastal areas. Eelgrass is a member of a group of land plants that migrated into the sea in relatively recent geologic times, and is not a seaweed.

Eelgrass grows by the spreading of rhizomes and by seed germination. Eelgrass flowers are hidden behind a transparent leaf sheath. Long filamentous pollen is released into the water, where it is spread by waves and currents. Both leaves and rhizomes contain lacunae, which are air spaces that provide buoyancy.

Eelgrass grows rapidly in shallow waters and is highly productive, thus providing habitats and food for many marine organisms in its stems, roots, leaves, and rhizomes. Eelgrass communities (meadows) provide many important ecological functions, including:

- anchoring of sediments with the spreading of rhizomes, which prevents **erosion** and provides stability
- decreasing the impact of waves and currents, resulting in a calm **environment** where organic materials and sediments can be deposited
- providing food, breeding areas, shelter and protective nurseries for marine organisms of commercial, recreational, and ecological importance
- concentrating nutrients from seawater that are then available for use in the food chain
- serving as food for water fowl and other animals such as snails and sea urchins
- as **detritus** (decaying plant matter), providing nutrition to organisms within the eelgrass community, in adjoining marshes, and in offshore sinks at depths up to 30,000 feet.

Eelgrass growth can be adversely impacted by human activities, including **dredging**, **logging**, shoreline or overwater construction, **power plants**, **oil spills**, **pollution**, and **species** invasion. Although transplantation projects designed to restore eelgrass meadows have been initiated on both coasts of the United States, creation of a large-scale meadow with the complex functions and relationships of a natural eelgrass system has not yet been achieved.

Effluent

The etymological meaning of this term is "flowing forth out of." For geologists, this word refers to a wide range of situations, from lava flowing from a **volcano** to a river flowing out of a lake. However, effluent is now most commonly used by environmentalists in reference to the **Clean**

Water Act of 1977. In this act, effluent is a **discharge** from a **point source**, and the legislation specifies allowable quantities of pollutants. These discharges are regulated under Section 402 of the act, and these standards must be met before these types of industrial and municipal wastes can be released into surface waters. *See also* Industrial waste treatment; Thermal pollution; Water pollution; Water quality

Effluent tax

Effluent tax refers to the fee paid by a company to **discharge** to a sewer. As originally proposed, the fee would have been paid for the privilege of discharging to the **environment**. However, there is presently no fee structure which allows a company, municipality, or person to contaminate the environment above the levels set by **water quality** criteria and effluent permits, unless fines levied by a regulatory agency could be deemed to be such fees.

Fees are now charged on the bases of simply being connected to a sewer and the types and levels of materials discharged to the sewer. For example, a municipality might charge all sewer customers the same rate for domestic sewage discharges below a certain flowrate. Customers discharging **wastewater** at a higher strength and/or flowrate would be assessed an incremental fee proportional to the increased amount of contaminants and/or flow. This charge is often referred to as a sewer charge, fee or surcharge.

There are cases in which wastewater is collected and tested to ensure that it meets certain criteria (e.g., required level of oil or a toxic metal, etc.) before it is discharged to a sewer. If the criteria are exceeded, the wastewater would require pretreatment. Holding the water before discharge is generally only practical when flowrates are low. In other situations, it may not be possible to discharge to a sewer because the treatment facility is unable to treat the waste; for example, many hazardous materials must be managed in a different manner.

Effluent taxes force dischargers to integrate environmental concerns into their economic plans and operational procedures. The fees cause firms and agencies to re-think **water conservation** policies, waste minimization, processing techniques and additives, and **pollution control** strategies. Effluent taxes, as originally proposed, might be instituted as an alternative to stringent regulation, but the sentiment of the current public and regulatory agencies is to block any significant degradation of the environment. It appears to be too risky to allow **pollution** on a fee basis, even when the fees are high. Thus, in the foreseeable future, effluents to the environment will continue to be controlled by means of effluent limits, water quality criteria, and fines. However, the taxing of effluents to a sewer is a viable means of challenging industries to enhance pollution control measures and stabilizing the performance of downstream treatment facilities.

E_H

A measure of the oxidation/reduction status of a natural water, **sediment** or **soil**. It is a relative electrical potential, measured with a potentiometer (e.g., a **pH** meter adjusted to read in volts) using an inert platinum electrode and a reference electrode (calomel or silver/silver chloride). E_H is reported in volts or millivolts, and is referenced to the potential for the oxidation of **hydrogen** gas to hydrogen ions (H^+). This electron transfer reaction is assigned a potential of zero on the relative potential scale. The oxidation and reduction reactions in natural systems are pH dependent and the interpretation of E_H values requires a knowledge of the pH. At pH 7, the E_H in water in equilibrium with the oxygen in air is +0.76v. The lowest possible potential is -0.4v when oxygen and other electron acceptors are depleted and **methane**, **carbon dioxide**, and hydrogen gas are produced by the decay of organic matter. *See also* Electron acceptor and donor

Paul Ralph Ehrlich (1932 –)

American population biologist and ecologist

Born in Philadelphia, Paul Ehrlich had a typical childhood during which he cultivated an early interest in entomology and zoology by investigating the fields and woods around his home. As he entered his teen years, Ehrlich grew to be an avid reader. He was particularly influenced by ecologist William Vogt's book, *Road to Survival* (1948), in which the author was the outlined the potential global consequences

of imbalance between the growing world population and level of food supplies available. This concept is one Ehrlich has discussed and examined throughout his career. After high school, Ehrlich attended the University of Pennsylvania where he earned his undergraduate degree in zoology in 1953. He received his master's degree from University of Kansas two years later and continued at the university to receive his doctorate in 1957. His degrees led to post-graduate work on various aspects of entomological projects, including observing flies on the Bering Sea, the behavioral characteristics of parasitic mites, and (his favorite) the population control of butterfly caterpillars with ants rather than pesticides. Other related field projects have taken him to Africa, Alaska, **Australia**, the South Pacific and South East Asia, Latin America, and **Antarctica**. His travels enabled him to learn first-hand the ordeals endured by those in overpopulated regions.

In 1954, he married Anne Fitzhugh Howland, biological research associate, with whom he wrote the best-selling book, *The Population Bomb* (1968). In the book, the Ehrlichs focus on a variety of factors contributing to overpopulation and, in turn, world hunger. It is evident throughout the book that the words and warnings of *The Survival Game* continued to exert a strong influence on Ehrlich. The authors warned that birth and death rates worldwide need to be "brought into line" before **nature** intervenes and renders (through **ozone layer depletion**, global warming, and **soil** exhaustion, among other **environmental degradation**) the human race extinct. Human reproduction, especially in highly developed countries like the United States, should be discouraged through levying taxes on diapers, baby food, and other related items; compulsory sterilization among the populations of certain countries should be enacted (the authors' feelings on *compulsory* sterilization have relaxed somewhat since 1968). Ehrlich himself underwent a vasectomy after the birth of the couple's first and only child.

In 1968, Ehrlich founded **Zero Population Growth**, Inc., an organization established to create and rally support for balanced population levels and the **environment**. He has been a faculty member at Stanford University (California) since 1959 and currently holds a full professor position there in the Biological Sciences Department. In addition, Ehrlich has been a news correspondent for NBC since 1989. In 1993, he was awarded the Crafoord Prize in **Population Biology** and the **Conservation** of Biological Diversity from the Royal Swedish Academy of Sciences and received the World **Ecology** Medal from the International Center for Tropical Ecology. In 1994, Ehrlich was bestowed with the **United Nations Environment Programme** Sasakawa Environment Prize.

Among Ehrlich's published works are *The Population Bomb* (1968), *The Cold and the Dark: The World After Nuclear War* (1984); *The Population Explosion* (1990); *Healing the Planet* (1991), *Betrayal of Science and Reason* (1996) which was written with his wife, and his most recent work, *Human Natures: Genes, Cultures, and the Human Prospect*, which was published in 2000. In 2001, Ehrlich was the recipient of the Distinguished Scientist Award. He continues his teaching as a professor of Population Studies at Stanford.

El Niño

El Niño is the most powerful weather event on the earth, disrupting weather patterns across half the earth's surface. Its three- to seven- year cycle brings lingering rain to some areas and severe **drought** to others. El Niño develops when currents in the Pacific Ocean shift, bringing warm water eastward from **Australia** toward Peru and Ecuador. Heat rising off warmer water shifts patterns of atmospheric pressure, interrupting the high-altitude wind currents of the jet stream and causing **climate** changes.

El Niño, "Christ child" or "the child" in Spanish, tends to appear in December. The phenomenon was first noted by Peruvian fishermen in the 1700s, who saw a warming of normally cold Peruvian coastal waters and a simultaneous disappearance of anchovy schools that provided their livelihood.

A recent El Niño began to develop in 1989, but significant warming of the Pacific did not begin until late in 1991, reaching its peak in early 1992 and lingering until 1995–the longest runing El Niño on record. Typically, El Niño results in unusual weather and short-term climate changes that cause losses in crops and **commercial fishing**. El Niño contributed to North America's mild 1992 winter, torrential **flooding** in southern California, and severe droughts in southeastern Africa. Wild animals in central and southern Africa died by the thousands, and 20 million people were plagued by **famine**. The dried **prairie** of Alberta, Canada, failed to produce wheat, and Latin America received record flooding. Droughts were felt in the Philippines, Sri Lanka, and Australia, and Turkey experienced heavy snowfall. The South Pacific saw unusual numbers of cyclones during the winter of 1992. El Niño's influence also seems to have suppressed some of the cooling effects of Mount Pinatubo's 1991 explosion.

Scientists mapping the sea floor of the South Pacific near Easter Island found one of the greatest concentration of active volcanoes on Earth. The discovery has intensified debate over whether undersea volcanic activity could change water temperatures enough to affect weather patterns in the Pacific. Some scientists speculate that periods of extreme volcanic activity underwater could trigger El Niño.

El Niño ends when the warm water is diverted toward to the North and South Poles, emptying the moving **reservoir** of stored energy. Before El Niño can develop again, the western Pacific must "refill" with warm water, which takes at least two years. *See also* Atmosphere; Desertification

Electric utilities

Utilities neither produce energy like oil companies nor consume it like households, but convert it from one form to another. The electricity created is attractive because it is clean and versatile, because it can be moved great distances nearly instantaneously. Demand for electricity has grown even as demand for energy as a whole has contracted, with consumption of electricity increasing from one quarter of total energy consumption in 1973 to about a third.

The major participants in the electric power industry are about 200 investor owned utilities that generate 78% of the power and supply 76% of the customers. The industry is very capital intensive and heavily regulated, and it has a large impact on other industries including **aluminum**, steel, electronics, computers, and robotics. The electrical power industry is the largest consumer of primary energy in the United States: consumes over one-third of the total national energy demand and only supplies one-tenth of that demand, losing from 65–75% of the energy in conversion, transmission, and distribution.

The electrical industry has been subjected to pressures and uncertainties which have had a profound impact on its economic viability, forcing it to reexamine numerous assumptions which previously governed its behavior. In the period after World War II, the main strategy the industry followed was to "grow and build." During this period demand increased at a rate of over 7% per year; new construction was needed to meet the growing demand, and this yielded economies of scale, with greater efficiencies and declining marginal costs. Public utility commissions lowered prices which stimulated additional demand. As long as prices continued to fall, demand continued to rise, and additional construction was necessary. New construction also occurred because the rate of return for the industry was regulated, and the only way for it to increase profits was to expand its rate base by building new plants and equipment.

This period of industry growth came to an end in the 1970s, primarily as a result of the energy crisis. Economic growth slowed and fuel prices escalated, including the weighted average cost of all **fossil fuels** and the spot market price of **uranium** oxide. As fuel prices rose, operating costs went up, and maintenance costs also increased, including the costs of supplies and materials, labor, and administrative expenses. All this led to higher costs per kilowatt hour, and as the price of electricity went up, sales growth declined.

The financial condition of the industry was further affected as capital costs for **nuclear power** and **coal power plants** increased. As the rate of inflation accelerated during this period, interest rates escalated. The rates utilities had to pay on bonds grew, and the costs of construction rose. The average cost of new generating capacity, as well as

installed capacity per kilowatt hour, went up. Net earnings and revenue per kilowatt hour went down, as both short-term and long-term debt escalated, and major generating units were cancelled and capital appropriations cut back.

During this decade, many people also came to believe that coal and nuclear power plants were a threat to the **environment**. They argued that new options had to be developed and that **conservation** was important. The federal government implemented new environmental and safety regulations which further increased utility costs. The government affected utility operations in other ways. In 1978 it deregulated interstate power sales, and required utilities to purchase alternative power such as **solar energy** from qualifying facilities at fully avoided costs. But perhaps the greatest transformation took place in the relationship electric power companies had to the public utility commissions. Once friendly, it deteriorated under the many economic and environmental changes that were then taking place. The size and number of requests for rate increases grew but the%age of requests granted actually went down.

By the end of the 1970s, the "grow and build" strategy was no longer tenable for the electric power industry. Since then, the industry has adopted many different strategies, with different segments following different courses based on divergent perceptions of the future. Almost all utilities have tried to negotiate long-term contracts which would lower their fuel-procurement costs, and attempts have also been made to limit the costs of construction, maintenance, and administration. Many utilities redesigned their rate structures to promote use when excess capacity was available and discourage use when it was not. Multiple rate structures for different classes of customers were also implemented for this purpose.

A number of utilities (Commonwealth Edison, Long Island Lighting, Carolina Power and Light, the TVA) have pursued a modified grow and build strategy based on the perception that economic growth would recover and that conservation and **renewable energy** would not be able to handle the increased demand. Some utilities (Consolidated Edison, Duke Power, General Public Utilities, Potomac Electric Power) pursued an option of capital minimization. They were located in areas of the country that were not growing and where the demand for power was decreasing. In areas of rapidly growing energy demand where regulations discouraged nuclear and coal plant construction, utilities such as Southern California Edison and Pacific Gas and Electric have had no option but to rely on their strong internal research and development capabilities and their progressive leadership to explore **alternative energy sources**. They have become energy brokers, buying alternative power from third party producers. Many utilities have also diversified, and the main attraction of diversification has been that it frees these companies from the profit limitations imposed by the public utility commissions. Outside the utility business (in real-estate, banking, and energy-related services), there was more risk but no limits on making money from profitable ventures. *See also* Alternative fuels; Economic growth and the environment; Energy and the environment; Energy conservation; Energy efficiency; Energy path, hard vs. soft; Energy policy; Geothermal energy; Wind energy

Electromagnetic field

Electromagnetic fields (EMFs) are low-level radiation generated by electrical devices, including power lines, household appliances, and computer terminals. They penetrate walls, buildings, and human bodies, and virtually all Americans are exposed to them, some to relatively high levels. Several dozen studies, conducted mainly over the last 15 years, suggest that exposure to EMFs at certain levels may cause serious health effects, including childhood **leukemia**, brain tumors, and damage to fetuses. But other studies show no such connections.

EMFs are strongest around power stations, high-current electric power lines, subways, movie projectors, handheld radar guns and large radar equipment, and microwave power facilities and relay stations. Common sources of everyday exposure include electric razors, hair dryers, computer video display terminals (VDTs), television screens, electric power tools, electric blankets, cellular telephones, and appliances such as toasters and food blenders.

The electricity used in North American homes, offices, and factories is called alternating current (AC) because it alternates the direction of flow at 60 cycles a second, which is called 60 hertz (Hz) power. Batteries, in contrast, produce direct current (DC). The electric charges of 60 Hz power create two kinds of fields: electric fields, from the strength of the charge, and magnetic fields, from its motion. These fields, taken together, are called electromagnetic fields, and they are present wherever there is electric power. A typical home exposes its residents to electromagnetic fields of 1 or 2 milligauss (a unit of strength of the fields). But under a high voltage power line, the EMF can reach 100–200 milligauss.

The electromagnetic spectrum includes several types of energy or radiation. The strongest and most dangerous are x-rays, gamma rays, and ultraviolet rays, all of which are types of **ionizing radiation**, the kind that contains enough energy to enter cells and atoms and break them apart. Ionizing radiation can cause **cancer** and even instant death at certain levels of exposure. The other forms of radiation are non-ionizing, and do not have enough energy to break up the chemical bonds holding cells together.

Microwave radiation constitutes the middle frequencies of the electromagnetic spectrum and includes radio frequency (RF), radar, and television waves, visible light and heat, and infrared radiation. Microwave radiation is emitted by VDTs, microwave ovens, satellites and earth terminals, radio and television broadcast stations, CB radios, security systems, and sonar, radar, and telephone equipment. Because of the pervasive presence of microwave radiation, virtually the entire American population is routinely exposed to it at some level. It is known that microwave radiation has biological effects on living cells.

The type of radiation generally found in homes is Extremely Low Frequency (ELF), and it has, until recently, not been considered dangerous, since it is non-ionizing and non-thermal. However, numerous studies over the last two decades provide evidence that the ELF range of EMFs can have serious biological effects on humans and can cause cancer and other health problems. Some scientists argue that the evidence is not yet conclusive or even convincing, but others contend that exposure to EMFs may represent a potentially serious public health problem.

After reviewing much of this evidence and data, the U. S. **Environmental Protection Agency** (EPA) released a draft report in December 1990 which determined that significant documentation exists linking EMFs to cancer in humans, and called for additional research on the matter. The study concluded that "...several studies showing leukemia, lymphoma, and cancer of the nervous system in children exposed to magnetic fields from residential 60-Hz electrical power distribution systems, supported by similar findings in adults in several occupational studies also involving electrical power frequency exposures, show a consistent pattern of response which suggests a causal link." The report went on to state that "evidence from a large number of biological test systems shows that ELF electric and magnetic fields induce biological effects that are consistent with several possible mechanisms of carcinogenesis...With our current understanding, we can identify 60-Hz magnetic fields from power lines and perhaps other sources in the home as a possible, but not proven, cause of cancer in humans."

EPA cited nine studies of cancer in children as supporting the strongest evidence of a link between the disease and EMFs stating that "these studies have consistently found modestly elevated risks (some statistically significant) of leukemia, cancer of the nervous system, and...lymphomas," with occupational studies furnishing "additional, but weaker, evidence" of EMFs raising the risk of cancer.

Concerning laboratory studies of the effects of EMFs on cells and the responses of animals to exposure, EPA found that "...there is reason to believe that the findings of carcinogenicity in humans are biologically plausible." EPA scientists further recommended classifying EMFs as a "class B-1 carcinogen," like cigarettes and **asbestos**, meaning that they are a probable source of human cancer.

Several of the studies done on EMFs show that children living near high voltage power lines, and workers occupationally exposed to EMFs from power lines and electrical equipment, are more than twice as likely to contract cancer, especially leukemia, as are children and workers with average exposure. One study found a five-fold increase in childhood cancer among families exposed to strong EMFs, and another study even documented the leukemia rate among children increasing in direct proportion to the strength of the EMFs. There are suspicions that EMFs may also be linked to the apparent dramatic rise in fatal brain tumors over recent years, which sometimes occur in clusters near power substations and other areas where EMFs are high. There is also concern about hand-held cellular telephones, whose antennae emit EMFs very close to the brain. But none of this evidence is considered conclusive.

Fetal damage has been cited as another possible effect of EMFs with higher-than-normal rates of miscarriages reported among pregnant women using electric blankets, waterbeds with electric heaters, and VDTs for a certain number of hours a day. But, other studies have failed to establish a link between EMFs and miscarriages.

In October, 1996, the **National Research Council** of the **National Academy of Sciences** issued an important report on the feared dangers of power lines, examining and analyzing over 500 published studies conducted over the previous 17 years. In announcing the report's findings, the

Council's panel of experts stressed that it could find no discernable hazard to human health from EMFs.

The announcement was hailed by the electric power industry, and widely reported in the news as disputing the alleged link between power lines and cancer. But what the report itself actually said was that there was "no conclusive and consistent evidence that shows that exposure to residential electric magnetic fields produce cancer...," a severe **burden of proof** indeed.

While the study did not find proof that electrical lines pose health hazards to humans, it did conclude that the association between proximity to power lines and leukemia in children was "statistically significant" and "robust." It observed that a dozen or so scientific studies had determined that children living near power lines are 1.5 times more likely to develop childhood leukemia than are other children.

Moreover, the study noted that 17 years of research had not identified any other factors that account for the increased cancer risk among children living near power lines. EMFs thus remain in the minds of many of the most likely albeit unproven cause of these cancers.

There are various theories to account for how EMFs may cause or promote cancer. Some scientists speculate that when cells are exposed to EMFs, normal cell division and DNA function can be disrupted, leading to genetic damage and increased cell growth and, thus, cancer. Indeed, research has shown that ELF fields can speed the growth of cancer cells, and make them more resistant to the body's immune system. The effects of EMFs on the cell membrane, on interaction and communication between groups of cells, and on the biochemistry of the brain are also being studied.

Hormones may also be involved. Weak EMFs are known to lower production of melatonin, a strong hormone secreted by the pineal gland, a tiny organ near the center of the brain. Melatonin strengthens the immune system and depresses other hormones that help tumors grow. This theory might help explain the tremendous increase in female breast cancer in developed nations, where electrical currents are so pervasive, especially the kitchen. The theory may also apply to electric razors, which operate in close proximity to the gland, and whose motors have relatively high EMFs. A 1992 study found that men with leukemia were more than twice as likely to have used an electric razor for over two-and-one-half minutes a day, compared with men who had not. The study also found weaker associations between leukemia and the use of hand-held massagers and hair dryers. Another hypothesis involves the motions of charged particles within EMFs, with calcium ions, for example, accelerating and damaging the structure of cell membranes under such conditions.

With conflicting and inconclusive data being cited by scientists and advocates on both sides of the debate, it is unlikely that the controversy over EMFs wil be resolved any time soon.

In October, 1996, the National Research Council of the National Academy of Sciences issued an important report on the feared dangers of power lines, examining and analyzing over 500 published studies conducted over the previous 17 years. In announcing the report's findings, the Council's panel of experts stressed that it could find no discernable hazard to human health from EMFs.

The announcement was hailed by the electric power industry, and widely reported in the news media as disputing the alleged link between power lines and cancer. But what the report itself actually said was that there was "no conclusive and consistent evidence that shows that exposure to residential electric magnetic fields produce cancer...".

While the study did not find proof that electrical lines pose health hazards to humans, it did conclude that the association between proximity to power lines and leukemia in children was "statistically significant" and "robust." It observed that a dozen or so scientific studies had determined that children living near power lines are 1.5 times more likely to develop childhood leukemia than are other children.

Moreover, the study noted that 17 years of research had not identified any other factors that account for the increased cancer risk among children living near power lines. EMFs thus remained, in the minds of many, the most likely—albeit unproven—cause of these cancers.

And a major five-year study, by the National Cancer Institute, the University of Minnesota, and other childhood leukemia specialists, published in July 1997 in *The New England Journal of Medicine,* found no evidence linking leukemia in children to electric power lines.

An electrostatic precipitator. (McGraw-Hill Inc. Reproduced by permission.)

Electron acceptor and donor

Electron acceptors are ions or molecules that act as oxidizing agents in chemical reactions. Electron donors are ions or molecules that donate electrons and are reducing agents. In the **combustion** reaction of gaseous **hydrogen** and oxygen to produce water (H_2O), two hydrogen atoms donate their electrons to an oxygen atom. In this reaction, the oxygen is reduced to an oxidation state of -2 and each hydrogen is oxidized to +1. Oxygen is an **oxidizing agent** (electron acceptor) and hydrogen is a reducing agent (electron donor). In **aerobic** (with oxygen) biological **respiration**, oxygen is the electron acceptor accepting electrons from organic **carbon** molecules; and as a result oxygen is reduced to -2 oxidation state in H_2O and organic carbon is oxidized to +4 in CO_2. In flooded soils, after oxygen is used up by aerobic respiration, nitrate, sulfate, as well as iron and manganese oxides can act as electron acceptors for microbial respiration. Other common electron acceptors include peroxide and hypochlorite (household bleach) which are bleaching agents because they can oxidize organic molecules. Other common electron donors include antioxidants like sulfite.

Electrostatic precipitation

A technique for removing **particulate** pollutants from waste gases prior to their exhaustion to a stack. A system of thin wires and parallel metal plates are charged by a high-voltage direct current (DC) with the wires negatively charged and the plates positively charged. As waste gases containing fine particulate pollutants (i.e., **smoke** particles, **fly ash**, etc.) are passed through this system, electrical charges are transferred from the wire to the particulates in the gases. The charged particulates are then attracted to the plates within the device, where they are then shaken off the plates during short intervals when the DC current is interrupted. (Stack gases can be shunted to a second parallel device during this period). They fall to a collection bin below the plates. Under optimum conditions, electrostatic precipitation is 99% efficient in removing particulates from waste gases.

Elemental analysis

Chemists have developed a number of methods by which they can determine the kind of elements present in a material and the amount of each element present. Nuclear magnetic resonance (NMR), flame spectroscopy, and **mass spectrometry** are examples of elemental analysis. These methods have been improved to a point where concentrations of a few **parts per million** of an element or less can be detected with relative ease. Elemental analysis is valuable in environmental work to determine the presence of a contaminant or pollutant. As an example, the amount of **lead** in a paint chip can be determined by means of elemental analysis.

Elephants

The elephant is a large mammal with a long trunk and tusks. The trunk is an elongated nose used for feeding, drinking, bathing, blowing dust, and testing the air. The tusks are upper incisor teeth composed entirely of dentine (ivory) used for defense, levering trees, and scraping for water. Elephants are long-lived (50–70 years) and reach maturity at 12 years. They reproduce slowly (one calf every two to three years) due to a 21-month gestation period and an equally long weaning period. A newborn elephant stands 3 ft (1 m) at the shoulder and weighs 200 lb (90 kg). The Elephantidae includes two living **species** and various extinct relatives.

Asian elephants (*Elephas maximus*) grow to 10 ft (3 m) high and weigh 4 tons. The trunk ends in a single lip, the forehead is high and domed, the back convex, and the ears small. Asian elephants are commonly trained as work animals. They range from India to southeast Asia. There are four subspecies, the most abundant of which is the Indian elephant (*E. m. bengalensis*) with a wild population of about 20,000. The Sri Lankan (*E. m. maximus*), Malayan (*E. m. hirsutus*), and the Sumatran elephants (*E. m. sumatranus*) are all endangered subspecies.

In Africa, adult bush elephants (*Loxodonta africana oxyotis*) are the world's largest land mammals, growing 11 ft (3.3 m) tall and weighing 6 tons. The trunk ends in a double lip, the forehead slopes, the back is hollow, and the ears are large and triangular. African elephants are also endangered and have never been successfully trained to work. The rare round-eared African forest elephant (*L. a. cyclotis*)

Elephants at the Amboseli National Park in Kenya, Africa. (Photograph by Wolfgang Kaehler. Corbis-Bettmann. Reproduced by permission.)

is smaller than the bush elephant and inhabits dense tropical rain forests.

Elephants were once abundant throughout Africa and Asia, but they are now threatened or endangered nearly everywhere because of widespread ivory **poaching**. In 1970 there were about 4.5 million elephants in Africa, by 1990 there were only 600,000. Protection from poachers and the 1990 ban on the international trade in ivory (which caused a drop in the price of ivory) are slowing the slaughter of African bush elephants. However, the relatively untouched forest elephants are now coming under increasing pressure. In West Africa recent **hunting** has reduced forest elephants to less than 3,000.

Elephants are **keystone species** in their ecosystems, and their elimination could have serious consequences for other **wildlife**. For example, wandering elephants disperse fruit seeds in their dung, and the seeds of some plants must pass through elephants to germinate. Elephants are also "bulldozer herbivores," habitually trampling plants and uprooting small trees. In African forests elephants create open spaces that allow the growth of vegetation favored by gorillas and forest antelope. In woodland **savanna** elephants convert wooded land into **grasslands**, thus favoring grazing animals. However, large populations of elephants confined to reserves can also destroy most of the vegetation in a region. Culling exploding elephant populations in reserves has been practiced in the past to protect the vegetation for other animals that depend on it.

Charles Sutherland Elton (1900 – 1991)

English ecologist

A factual, accurate, complete history of **ecology** as a discipline has yet to be written. When that history is finally compiled, the British ecologist Charles Sutherland Elton will stand as one of the disciplines leading mentors of the twentieth century.

Charles Elton was born March 29, 1900, in Manchester, England. His interest in what he later called "scientific natural history" was sparked early by his older brother Geoffrey. By the age of 19, Charles Elton was already investigating **species** relationships in ponds, streams, and sand-dune areas around Liverpool.

His formal education in ecology was shaped by an undergraduate education at Oxford University, and by his participation in three scientific expeditions to Spitsbergen in the Arctic (in 1921, 1923, and 1924), the first one as an assistant to Julian Huxley. Even though an undergraduate, he was allowed to begin an ecological survey of animal life in Spitsbergen, a survey completed on the third trip. These experiences and contacts led him to a position as biological consultant to the Hudson's Bay Company, which he used to conduct a long-term study of the fluctuations of fur-bearing mammals, drawing on company records dating back to 1736.

During this period, Elton became a member of the Oxford University faculty (in 1923), and was eventually elected a senior research fellow of Corpus Christie College. His whole academic career was spent at Oxford, from which he retired in 1967.

He applied the skills and insights gained through the Spitsbergen and Hudson Bay studies to work on the fluctuations of mice and voles in Great Britain. To advance and coordinate this work, he started the Bureau of Animal Populations at Oxford. This institution (and Elton's leadership of it) played a vital role in the shaping of research in animal ecology and in the training and education of numerous ecologists in the early twentieth century.

Elton published a number of books, but four proved to be of particular significance in ecology. He published his first book, *Animal Ecology*, in 1929, a volume now considered a classic, its author one of the pioneers in the field of ecology, especially animal ecology. In the preface to a 1966 reissue, Elton suggested that the book "must be read as a pioneering attempt to see...the outlines of the subject at a period when our knowledge [of] terrestrial communities was of the roughest, and considerable effort was required to shake off the conventional thinking of an earlier zoology and enter upon a new mental world of populations, inter-relations, movements and communities—a world [of] direct study of natural processes..." Major topics in that book remain major topics in ecology today: the centrality of trophic relationships; the significance of **niche** as a functional concept; ecological **succession**; the dynamics of dispersal; and the relationships critical to the fluctuation of animal populations, including interactions with **habitat** and physical **environment**.

His year of work on small mammals in Spitzbergen, for the Hudson's Bay Company, and in British localities accessible to Oxford, culminated in the publication, in 1942, of *Voles, Mice and Lemmings*. This work, still in print almost 60 years later, "brought together...his own work and a collection of observations from all over the world and from ancient history onward." Elton begins the book by establishing a context of "vole and mouse plagues" through history. A second section is on population fluctuations in north-west Europe, voles and mice in Britain, but also lemmings in Scandinavia. The other two sections focus on **wildlife** cycles in northern Labrador, including chapters on fox and marten, voles, foxes, the lemmings again, and caribou herds. In all this work, the emphasis is on the dynamics of change, on the constant interactions and subsequent fluctuations of these various populations and often stringent environments.

Elton's 1958 book, *The Ecology of Invasions by Animals and Plants*, focused on a problem that is of even more concern today—the arrival and impact of **exotic species** introduced from other places, sometimes naturally, increasingly through the actions of humans. As always, Elton is careful to set the historical context by showing how biological "invaders" have been moving around the globe for a long time, but he also emphasizes that "we are living in a period of the world's history when the mingling of thousands of kinds of organisms from different parts of the world is setting up terrific dislocations in nature."

The Pattern of Animal Communities, published in 1966, emerged from years of surveying species, populations, communities and habitats in the Wytham Woods not far from Oxford. In this book, his primary intent was to describe and classify the diverse habitats available to terrestrial animals, and most of the chapters of the book are given to specific habitats for specialized kinds of organisms. Though not generally considered a theoretical ecologist, his early thinking did help to shape the field. In this book, late in his career, he summarized that thinking in a chapter titled "The Whole Pattern," in which he presents a set of fifteen "new concepts of the structure of natural systems," which he stated as a "series of propositions," though some reviewers labeled them "principles" of ecology.

Always the pragmatist, Elton devoted considerable time to the practical, applied aspects of ecology. Nowhere is this better demonstrated than in the work he turned to early in World War II. One of his original purposes in establishing the Bureau of Animal Populations was to better understand the role of disease in the fluctuations of animal

numbers. At the beginning of the war, he turned the research focus of the Bureau to the control of rodent pests, especially to help in controlling human disease and to contribute toward the reduction of crop losses to rodents.

Elton was an early conservationist, stating in the preface to his 1927 text that "ecology is a branch of zoology which is perhaps more able to offer immediate practical help to mankind than any of the others [particularly important] in the present rather parous state of civilization." Elton strongly advocated the preservation of biological diversity, and pressed hard for the prevention of extinctions; this is what he emphasizes in his chapter on "The Reasons for Conservation" in the *Invasions* book. But he also expanded his conception of **conservation** to mean looking for some "general basis for understanding what it is best to do" and "looking for some wise principle of co-existence between man and **nature**, even if it has to be a modified kind of man and a modified kind of nature." He even took the unusual step (unusual for professional ecologists in his time and still unusual today) of going into the broadcast booth to popularize the importance of ecology in helping to achieve those goals though environmental management as applied ecology.

Elton's service to ecology as a learned discipline was enormous. In the early twentieth century, ecology was still in its formative years, so Elton's ideas and contributions came at a critical time. He took the infant field of animal ecology to maturity, building it to a status equal that of the more established plant ecology. His research Bureau at Oxford fostered innovative research and survey methods, and provided early intellectual nurture and professional development to ecologists who went on to become major contributors to the field, one example being the American ecologist Eugene Odum. As its first editor, Elton was "in a very real sense the creator" of the *Journal of Animal Ecology*, serving in the position for almost twenty years. He was one of the founders of the British Ecological Society. Elton's books and ideas continue to influence ecologists today.

Emergency Planning and Community Right-to-Know Act (1986)

The Emergency Planning and Community **Right-to-Know** Act (EPCRA), also known as Title III, is a statute enacted by Congress in 1986 as a part of the Superfund Amendments and Reauthorization Act (SARA). It was enacted in response to public concerns raised by the accidental release of poisonous gas from a Union Carbide plant in **Bhopal, India** which killed over 2,000 people.

EPCRA has two distinct yet complementary sets of provisions. First, it requires communities to establish plans for dealing with emergencies created by chemical leaks or spills and defines the general structure these plans must assume. Second, it extends to communities the same kind of right-to-know provisions which were guaranteed to employees earlier in the 1980s. Overall, EPCRA is an important step away from crisis-by-crisis **environmental enforcement** toward a proactive or preventative approach. This proactive approach depends on government monitoring of potential environmental hazards, which is being accomplished by using computerized files of data submitted by businesses.

Under the provisions of EPCRA, the governors of every state were required to establish a State Emergency Response Commission by 1988. Each state commission was required in turn to establish various emergency planning districts and to appoint a local emergency planning committee for each. Each committee was required to prepare plans for potential chemical emergencies in their communities, which includes the identities of facilities, the procedures to be followed in the event of a chemical release, and the identities of community emergency coordinators as well as a facility coordinator from each business subject to EPCRA.

A facility is subject to EPCRA if it has a substance in a quantity equal to or greater than the threshold planning quantity specified on a list of about 400 extremely hazardous substances published by the **Environmental Protection Agency**. Also, after public notice and comment either the state governor or the State Emergency Response Commission may designate facilities to be covered outside of these guidelines. Each covered facility is required to provide facility notification information to the state commission and to designate a facility coordinator to work with the local planning committee.

EPCRA requires these facilities to report immediately any accidental releases of **hazardous material** to the Community Coordinator of its local emergency committee. There are two classifications for such hazardous substances. The substance must be either on the EPA's extremely hazardous substance list, or defined under the Comprehensive Environmental Response Compensation and Liability Act (CER-

CLA). In addition to the initial emergency notice, follow-up notices and information are required.

EPCRA's second major set of provisions is designed to establish and implement a community right-to-know program. Information about the presence of **chemicals** at facilities within the community is collected from businesses and made available to public officials and the general public. Businesses must submit two sets of annual reports: the Hazardous Chemical Inventory and Toxic Chemicals Release Inventories (TRIs), also known as Chemical Release Forms.

For the Hazardous Chemical Inventory, each facility in the community must prepare or obtain a Material Safety Data Sheet for each chemical on its premises meeting the threshold quantity. This information is then submitted to the Local Emergency Planning Committee, the local fire department, and the State Emergency Response Commission. These data sheets are identical to those required under the Occupational Safety and Health Act's worker right-to-know provisions. For each chemical reported in the Hazardous Chemical Inventory, a Chemical Inventory Report must be filed each year.

The second set of annual reports required as a part of the community right-to-know program is the Toxic Release Inventory (TRI), which must be filed annually. Releases reported on this form include even those made legally with permits issued by the EPA and its state counterparts. Releases made by the facility into air, land, and water during the preceding twelve months are summarized in this inventory. The form must be filed by companies having ten or more employees if that company manufactures, stores, imports, or otherwise uses designated toxic chemicals at or above threshold levels.

The information submitted pursuant to both the emergency planning and the right-to-know provisions of EPCRA is available to the general public through the Local Emergency Planning Committees. In addition, health professionals may obtain access to specific chemical identities even if that information is claimed by the business to be a trade secret in order to treat exposed individuals or protect potentially exposed individuals.

During the late 1980s, the EPA and its state counterparts emphasized public awareness and education about the requirements of EPCRA, rather than enforcement. But Congress has provided stiff penalties for noncompliance, and these agencies have now begun to implement their enforcement tools. Civil penalties of up to $25,000 per day for a first violation and up to $75,000 per day for a second may be assessed against a business failing to comply with reporting requirements, and citizens have the right to sue companies that fail to report. Further, enforcement by the government may include criminal prosecution and imprisonment.

In June of 1996, in response to community pressure, the U.S. Congress took up its first major vote on Community Right to Know since 1986. In the 1996 vote, the House of Representatives removed provisions from an EPA budget appropriation which would have made substantial cuts in funds allocated to compiling of Toxics Release Inventories (TRI). In addition, Congress passed an EPA proposal that added seven additional industries to the number of industries which must report under TRI, thus bringing the total number of industries required to report to twenty-seven. Those twenty-seven include more than 31,000 facilities across the United States. These Congressional votes are viewed by environmentalists as victories for right to know. Looking ahead, EPCRA may be further strengthened through provisions included in The Children's Environmental Protection and Right to Know Act of 1997 which was introduced to Congress in May of 1997 by Rep. Henry Waxman (D) and Rep. Jim Saxtan (Republican).

Studies have revealed that EPCRA has had far-reaching effects on companies and that industrial practices and attitudes toward chemical risk management are changing. Some firms have implemented new **waste reduction** programs or adapted previous programs. Others have reduced the potential for accidental releases of hazardous chemicals by developing safety audit procedures, reducing their chemical inventories, and using less hazardous chemicals in their operations.

As information included in reports such as the annual **Toxics Release Inventory** has been disseminated throughout the community, businesses have found they must be concerned with risk communication. Various industry groups throughout the United States have begun making the information required by EPCRA readily available and helping citizens to interpret that information. For example, the Chemical Manufacturers Association has conducted workshops for its members on communicating EPCRA information to the community and on how to communicate about risk in general. Similar seminars are now made available to businesses and their employees through trade associations, universities, and other providers of continuing education. *See also* Chemical spills; Environmental monitoring; Environmental Monitoring and Assessment Program; Hazardous Materials Transportation Act; Toxic substance; Toxic Substances Control Act; Toxics use reduction legislation

Emergent diseases (human)

Although many diseases such as measles, pneumonia, and pertussis (whooping cough) have probably inflicted humans for millennia, at least 30 new infectious diseases have appeared in the past two decades, In addition, many well-known diseases recently have reappeared in more virulent or drug-resistant forms. An emergent disease is one never known before or one that has been absent for at least 20 years. **Ebola** fever is a good example of an emergent disease. A kind of viral hemorrhagic fever, Ebola is extremely contagious and often kills up to 90% of those who are exposed to it. The disease was unknown until about 20 years ago, but is thought to have been present in monkeys or other primates. Killing and eating chimps, gorillas, and other primates is thought to be the route of infection in humans. **AIDS** is another disease that appears to have suddenly moved from other primates to humans. How pathogens suddenly move across **species** barriers to become highly contagious and terribly lethal is one of the most important questions in **environmental health**.

Some of the most devastating epidemics have occurred when travelers bring new germs to a naïve population lacking immunity. An example was the **plague**, or Black Death, which swept through Europe and Western Asia repeatedly in the fourteenth and fifteenth centuries. During the first- and worst-episode between 1347 and 1355, about half the population of Europe died. In some cities the **mortality** rate was as high as 80%. It's hard to imagine the panic and fear this disease caused. An even worse disaster may have occurred when Europeans brought smallpox, measles, and other infectious diseases to the Americas. By some calculations, up to 90% of the native people perished as diseases swept through their population. One reason European explorers thought the land was an empty **wilderness** was that these diseases spread out ahead of them, killing everyone in their path.

Probably the largest loss of life from an individual disease in a single year was the great influenza pandemic of 1918. Somewhere between 30 and 40 million people succumbed to this **virus** in less than 12 months. This was more than twice the total number killed in all the battles of World War I, which was occurring at the time. Crowded, unsanitary troop ships carrying American soldiers to Europe started the epidemic. War refugees, soldiers from other nations returning home, and a variety of other travelers quickly spread the virus around the globe. Flu is especially contagious, spreading either by direct contact with an infected person or by breathing airborne particles released by coughing or sneezing. Most flu strains are zoonotic (transmitted from an animal host to humans). Pigs, birds, monkeys, and rodents often serve as reservoirs from which viruses can jump to humans. Although new flu strains seem to appear nearly every year, no epidemic has been as deadly as that of 1918.

Malaria, the most deadly of all insect-borne diseases, is an example of the return of a disease that once was thought nearly vanquished. Malaria now claims about 3 million lives every year—90% in Africa and most of them children. With the advent of modern medicines and pesticides, malaria had nearly been wiped out in many places but recently has had a resurgence. The protozoan parasite that causes the disease is now resistant to most antibiotics, while the mosquitoes that transmit it have developed **resistance** to many insecticides. Spraying of DDT in India and Sri Lanka reduced malaria from millions of infections per year to only a few thousand in the 1950s and 1960s. Now South Asia is back to its pre-DDT level of some 2.5 million new cases of malaria every year. Other places that never had malaria or dengue fever now have them because of **climate** change and **habitat** alteration. Gulf-coast states in America, for example, are now home to the *Aedes aegypti* mosquito that carries these diseases.

Why have vectors such as mosquitoes and pathogens such as the malaria parasite become resistant to pesticides and antibiotics? Part of the answer is natural selection and the ability of many organisms to evolve rapidly. Another factor is the human tendency to use control measures carelessly. When we discovered that DDT and other insecticides could control mosquito populations, we spread them indiscriminately without much thought to ecological considerations. In the same way, antimalarial medicines such as chloroquine were given to millions of people, whether they showed symptoms or not. This was a perfect recipe for natural selection. Many organisms were exposed only minimally to control measures. This allowed those with natural resistance to outcompete others and spread their genes through the population. After repeated cycles of exposure and selection, many **microorganisms** and their vectors are insensitive to almost all our weapons against them.

There are many examples of drug resistance in pathogens. Tuberculosis (TB), once the foremost cause of death in the world, had nearly been eliminated—at least from the developed world—by the end of the twentieth century. Drug-resistant varieties of TB are now spreading rapidly, however. One of the places these strains arise is in Russia, where crowded prisons with poor **sanitation**, little medical care, gross overcrowding, and inadequate nutrition serve as a breeding ground for this deadly disease. Inmates who are treated with antibiotics rarely get a complete dose. Those

with TB aren't segregated from healthy inmates. Patients with active TB are released from prison and sent home to spread the disease further. And migrants from Russian carry the disease to other countries.

Another development is the appearance of drug-resistant strains of *Staphylococcus aureus*, the most common form of hospital-acquired infections. Staph A has many forms, some of which are extremely toxic—toxic-shock syndrome is one where staphylococcus **toxins** spread through the body and sometimes bring death in a matter of just hours. Another strain of staphylococcus, sometimes called flesh-eating bacteria, causes massive necrosis (cell death) that destroys skin, connective tissue, and muscle. For 40 years vancomycin has been the last recourse against staph infections. Strains resistant to everything else could be controlled by this antibiotic. Now vancomycin-resistant staph strains are being reported in many places.

A number of factors contribute currently to the appearance and spread of these highly contagious diseases. With 6 billion people now inhabiting the planet, human densities are much higher, enabling germs to spread further and faster than ever before. Expanding populations push into remote areas encountering new pathogens and **parasites**. Environmental change on a larger scale, such as cutting forests, creating unhealthy urban surroundings, and causing global-climate change, among other things, eliminates predators and habitat changes favor disease-carrying organisms such as mice, rats, cockroaches, and mosquitoes.

Another important factor in the spread of many diseases is the speed and frequency of modern travel. Millions of people go every day from one place to another by airplane, boat, train, or **automobile**. Very few places on earth are more than 24 hours by jet plane from any other place. Many highly virulent diseases take several days for symptoms to appear.

Humans aren't the only ones to suffer from new and devastating diseases. Domestic animals and **wildlife** also experience sudden and widespread epidemics, sometimes called **emergent ecological diseases**. In 1998, for example, a distemper virus killed half the **seals** in Western Europe. It's thought that toxic pollutants and hormone-disrupting environmental **chemicals** might have made seals and other marine mammals susceptible to infections. In 2002, more dead seals were found in Denmark, raising fears that distemper might be reappearing.

Chronic wasting disease (CWD) is spreading through deer and elk populations in the North America. Caused by a strange protein called a prion, CWD is one of a family of irreversible, degenerative neurological diseases known as transmissible spongiform encephalopathies (TSE) that include **mad cow disease** in cattle, scrapie in sheep, and Creutzfelt-Jacob disease in humans. CWD probably started when elk ranchers fed contaminated animal by-products to their herds. Infected animals were sold to other ranches, and now the disease has spread to wild populations. First recognized in 1967 in Saskatchewan, CWD has been identified in wild deer populations and ranch operations in at least eight American states. No humans are known to have contracted TSE from deer or elk, but there is a concern that we might see something like the mad cow disaster that inflicted Europe in the 1990s. At least 100 people died, and nearly five million European cattle and sheep were slaughtered in an effort to contain that disease.

One of the things all these diseases have in common is that human-caused environmental changes are stressing biological communities and upsetting normal ecological relationships.

Emergent ecological diseases

Emergent ecological diseases are relatively recent phenomena involving extensive damage being caused to natural communities and ecosystems. In some cases, the specific causes of the ecological damage are known, but in others they are not yet understood.

Examples of relatively well-understood ecological diseases mostly involve cases in which introduced, non-native pathogens are causing extensive damage. There are, unfortunately, many examples of this kind of damage caused by invasive organisms. One case involves the introduced chestnut blight fungus (*Endothia parasitica*), which has virtually eliminated the once extremely abundant American chestnut (*Castanea dentata*) from the hardwood forests of eastern North America. A similar ongoing pandemic involves the Dutch elm disease fungus (*Ceratocystis ulmi*), which is removing white elm (*Ulmus americana*) and other native elms from

North America. Some introduced insects are also causing important forest damage, including the effects of the balsam wooly adelgid (*Adelges picea*) on Fraser fir (*Abies fraseri*) in the Appalachian Mountains.

Other cases of ecological diseases involve widespread damages that are well-documented, but the causes of which are not yet understood. One of them affects native forests of Hawaii dominated by the tree ohia (*Metrosideros polymorpha*). For some unknown reason, stands of ohia decline and then die when they reach maturity. This may be caused by the synchronous senescence of a cohort of trees that established following a stand-replacing disturbance, such as a lava flow, and then reached maximum longevity at about the same time. Other causal factors have, however, also been suggested, including **nutrient** dysfunction and pathogens.

Another case is known as birch decline, which occurred over great regions of the northeastern United States and eastern Canada from the 1930s to the 1950s. The disease affected yellow birch (*Betula alleghaniensis*), paper birch (*B. papyrifera*), and grey birch (*B. populifolia*), which suffered **mortality** over a huge area. The specific cause of this extensive forest damage was never determined, but it could have involved the effects of freezing ground conditions during winters with little snow cover.

Rather similar forest declines and diebacks have affected red spruce (*Picea rubens*) and sugar maple (*Acer saccharum*) in the same broad region of eastern North America during the 1970s to 1990s. Although the causes of these forest damages are not yet fully understood, it is thought that **air pollution** or acidifying **atmospheric deposition** may have played a key role. In western Europe, extensive declines of Norway spruce (*Picea abies*) and beech (*Fagus sylvatica*) are also thought to somehow be related to exposure to air **pollution** and **acidification**. In comparison, the damage caused by **ozone** to forests dominated by ponderosa pine (*Pinus ponderosa*) in California is a relatively well-understood kind of emergent ecological disease.

In the marine realm, widespread damage to diverse **species** of corals has been documented in far-flung regions of the world. The phenomenon is known as coral "bleaching," and it involves the corals expelling their symbiotic algae (known as zooxanthellae), often resulting in death of the coral. **Coral bleaching** is thought to possibly be related to **climate** warming, although it can be caused by both unusually high or low water temperatures, changes in **salinity**, and other environmental stresses.

Another unexplained case of an ecological disease appears to be afflicting species of amphibians in many parts of the world. The amphibian declines involve severe population collapses, and have even caused the **extinction** of some species. The specific causes are not yet known, but they likely involve introduced **microbial pathogens**, or possibly increased exposure to solar **ultraviolet radiation**, climate change, or some other factor.

Emission

Release of material into the **environment** either by natural or human-caused processes. This term is used especially in describing **air pollution** for volatile or suspended contaminants that result from processes such as burning fuel in an engine. Definitions of **pollution** are complicated by the fact that many of the materials that damage or degrade our **atmosphere** have both human and natural origins. Volcanoes emit ash, **acid** mists, **hydrogen** sulfide, and other toxic gases. Natural forest fires release **smoke**, soot, carcinogenic **hydrocarbons**, dioxins, and other toxic **chemicals** as well as large amounts of **carbon dioxide**. Do these emissions constitute pollution when they originate from human sources but not if released by natural processes? Is it reasonable to restrict human emissions if there are already very large natural sources of those same materials in the environment? An important consideration in answering these questions lies in the regenerative capacity of the environment to remove or neutralize contaminants. If we overload that capacity, a marginal additional emission may be important. Similarly, if there are thresholds for response, an incremental addition to ambient levels may be very important.

Emission standards

Federal, state, and local stack and **automobile** exhaust **emission** limits that regulate the quantity, rate, or concentration of emissions. Emission standards can also regulate the opacity of plumes of **smoke** and dust from point and area emission sources. They can also assess the type and quality of fuel and the way the fuel is burned, hence the type of technology used. With the exception of **plume** opacity, such standards are normally applied to the specific type of source for a given pollutant. Federal standards include New Source Performance Standards (NSPS) and **National Emission Standards for Hazardous Air Pollutants** (NESHAPS).

Emission standards may include prohibitory rules that restrict existing and new source emission to specific emission concentration levels, mass emission rates, plume opacity, and emissions relative to process throughput emission rates. They may also require the most practical or best available technology in case of new emission in pristine areas.

New sources and modifications to existing sources can be subject to new source permitting procedures which require technology-forcing standards such as **Best Available Control Technology** and **Lowest Achievable Emission Rate** (LAER). However, these standards are designed to consider the changing technological and economic feasibility of evermore stringent emission controls. As a result, such requirements are not stable and are determined through a process involving discretionary judgements of appropriateness by the governing **air pollution** authority. *See also* Point source

Emissions trading

see **Trade in pollution permits**

Emphysema

Emphysema is an abnormal, permanent enlargement of the airways responsible for gas-exchange in the lungs. Primary emphysema is commonly linked to a genetic deficiency of the **enzyme** &agr;$_1$-antitrypsin which is a major component of &agr;$_1$-globulin, a **plasma** protein. Under normal conditions &agr;$_1$-antitrypsin inhibits the activity of many proteolytic enzymes which breakdown proteins. This results in the increased likelihood of developing emphysema as a result of proteolysis (breakdown) of the lung tissues.

Emphysema begins with destruction of the alveolar septa. This results in "air hunger" characterized by labored or difficult breathing, sometimes accompanied by pain. Although emphysema is genetically linked to deficiency in certain enzymes, the onset and severity of asthmatic symptoms has been definitively linked to irritants and pollutants in the **environment**. A significantly greater proportion of the individuals manifesting emphysemic symptoms is observed in smokers, populations clustered around industrial complexes, and **coal** miners. *See also* Asthma; Cigarette smoke; Respiratory diseases

Endangered species

An "endangered species" under United States law (the **Endangered Species Act** [1973]) is a creature "in danger of **extinction** throughout all or a significant portion of its range." A "threatened" **species** is one that is likely to become endangered in the foreseeable future.

For most people, the endangered species problem involves the plight of such well-known animals as eagles, **tigers**, **whales**, **chimpanzees**, **elephants**, **wolves**, and whooping cranes. However, literally millions of lesser-known or unknown species are endangered or becoming so, and the loss of these life forms could have even more profound effects on humans than that of large mammals with whom we more readily identify and sympathize.

Most experts on species extinction, such as Edward O. Wilson of Harvard and Norman Myers, estimate current and projected *annual* extinctions at anywhere from 15,000 to 50,000 species, or 50 to 150 *per day*, mainly invertebrates such as insects in tropical rain forests. At this rate, 5–10% of the world's species, perhaps more, could be lost in the next decade and a similar percentage in coming decades.

The single most important common threat to **wildlife** worldwide is the loss of **habitat**, particularly the destruction of biologically-rich tropical rain forests. Additional factors have included commercial exploitation, the introduction of non-native species, **pollution**, **hunting**, and **trapping**. Thus, we are rapidly losing a most precious heritage, the diversity of living species that inhabit the earth. Within one generation, we are witnessing the threatened extinction of between one fifth and one half of all species on the planet.

Species of wildlife are becoming extinct at a rate that defies comprehension and threatens our own future. These losses are depriving this generation and future ones of much of the world's beauty and diversity, as well as irreplaceable sources of food, drugs, medicines, and natural processes that are or could prove extremely valuable, or even necessary, to the well-being of our society.

Today's rate of extinction exceeds that of all of the **mass extinction** in geologic history, including the disappearance of the dinosaurs 65 million years ago. It is impossible to know how many species of plants and animals we are actually losing, or even how many species exist, since many have never been "discovered" or identified. What we do know is that we are rapidly extirpating from the face of the earth countless unique life forms that will never again exist.

Most of these species extinctions will occur—and are occurring—in tropical rain forests, which are the richest biological areas on earth and are being cut down at a rate of 1–2 acres (0.4–0.8 ha) a second. Although tropical forests cover only about 5–7% of the world's land surface, they are thought to contain over half of the species on earth.

There are more bird species in one Peruvian preserve than in the entire United States. There are more species of fish in one Brazilian river than in all the rivers of the United States. And a single square mile in lowland Peru or Amazonian Ecuador or Brazil may contain over 1500 species of butterflies, more than twice as many as are found in all of

the United States and Canada. Half an acre of Peruvian **rain forest** may contain over 40,000 species of insects.

Eric Eckholm in *Disappearing Species: The Social Challenge* notes that when a plant species is wiped out, some 10–30 dependent species can also be jeopardized, such as insects and even other plants. An example of the complex relationship that has evolved between many tropical species is the 40 different kinds of fig trees native to Central America, each of which has a specific insect pollinator. Other insects, including pollinators for other plants, depend on certain of these fig trees for food.

Thus, the extinction of one species can set off a chain reaction, the ultimate effects of which cannot be foreseen. As Eckholm puts it, "Crushed by the march of civilization, one species can take many others with it, and the ecological repercussion and arrangements that follow may well endanger people." The loss of so many unrecorded, unstudied species will deprive the world not only of beautiful and interesting life forms, but also much-needed sources of medicines, drugs, and food that could be of critical value to humanity. Every day, we could be losing plants that could provide cures for **cancer** or **AIDS** or could become food staples as important as rice, wheat, or corn. We will simply never know the value or importance of the untold thousands of species vanishing each year.

As of spring of 2002, the U.S. Department of the Interior's list of endangered and threatened species included 1,070 animals (mammals, birds, reptiles, amphibians, fish, snails, clams, crustaceans, insects, and arachnids), and 746 plants, for a total of 1816 endangered or threatened species.

Under the Endangered Species Act, the Department of the Interior is given general responsibility for listing and protecting endangered wildlife, except for marine species (such as whales and **seals**), which are the responsibilities of the Commerce Department.

In addition, the United States is subject to the provisions of the Convention on International Trade in Endangered Species of Wild Flora and **Fauna** (CITES), which regulates global commerce in **rare species**. But in many cases, the government has not been enthusiastic about administering and enforcing the laws and regulations protecting endangered wildlife. Conservationists have for years criticized the Interior Department for its slowness and even refusal to list hundreds of endangered species that, without government protection, were becoming extinct. Indeed, the Department admits that some three dozen species have become extinct while undergoing review for listing.

In December 1992, the department settled a lawsuit brought by animal protection groups by agreeing to expedite the listing process for some 1300 species and to take a more comprehensive "multispecies, **ecosystem** approach" to protecting wildlife and their habitat. In October 1992, at the national conference of the **Humane Society of the United States** held in Boulder, Colorado, the Secretary of the Interior Bruce Babbitt in his keynote address lauded the Endangered Species Act as "an extraordinary achievement," emphasized the importance of preserving endangered species and biological diversity, and noted: "The extinction of a species is a permanent loss for the entire world. It is millions of years of growth and development put out forever." *See also* Biodiversity

Endangered Species Act (1973)

The **Endangered Species** Act (ESA) is a law designed to save **species** from **extinction**. What began as an informal effort to protect several hundred North American vertebrate species in the 1960s has expanded into a program that could involve hundreds of thousands of plant and animal species throughout the world. As of May 2002, 1,816 species were listed as endangered or threatened, 1,258 in the United States and 558 in other countries. The law has become increasingly controversial as it has been viewed by commercial interests as a major impediment to economic development. This issue recently came to a head in the Pacific Northwest, where the **northern spotted owl** has been listed as threatened. This action has had significant affects on the regional forest products industry. The ESA was due to be re-authorized in 1992, but this was postponed due to that year's election. Although it expired on October 1, 1992, Congress has allotted enough funds to keep the ESA active.

Government action to protect endangered species began in 1964, with the formation of the Committee on Rare and Endangered Wildlife Species within the Bureau of Sport Fisheries and Wildlife (now the **Fish and Wildlife Service** [FWS]) in the **U.S. Department of the Interior**. In 1966, this committee issued a list of 83 native species (all verte-

A chart of the estimated annual rate of species loss from 1700–2000. (Beacon Press. Reproduced by permission.)

brates) that it considered endangered. Two years later, the first act designed to protect species in danger of extinction, the Endangered Species Preservation Act of 1966, was passed. The Secretary of the Interior was to publish a list, after consulting the states, of native vertebrates that were endangered. This law directed federal agencies to protect endangered species when it was "practicable and consistent with the primary purposes" of these agencies. The taking of listed endangered species was prohibited only within the **national wildlife refuge** system; that is, species could be killed almost anywhere in the United States. Finally, the law authorized the acquisition of **critical habitat** for these endangered species.

In 1969, the Endangered Species Conservation Act was passed, which included several significant amendments to the 1966 Act. Species could now be listed if they were threatened with worldwide extinction. This substantially broadened the scope of species to be covered, but it also limited the listing of specific populations that might be endangered in some parts of the United States but not in danger elsewhere (e.g., grizzly bears, bald eagles, timber **wolves**, all of which flourish in Canada and Alaska). The 1969 law stated that mollusks and crustaceans could now be included on the list, further broadening of the scope of the law. Finally, trade in illegally taken endangered species was prohibited. This substantially increased the protection offered such species, compared to the 1966 law.

The Endangered Species Act of 1973 built upon and strengthened the previous laws. The impetus for the law was a call by President Nixon in his state of the union message for further protection of endangered species and the concern in Congress that the previous acts were not working well enough. The goal of the ESA was to protect all endangered species through the use of "all methods and procedures necessary to bring any endangered or threatened species to the point at which the measures provided pursuant to [the] Act are no longer necessary." In other words, the goal was to bring endangered species to full recovery. This goal, like others included in environmental legislation at the time, was unrealistic. The ESA also expanded the number of species that could be considered for listing to all animals (except those considered pests) and plants. It stipulated that the listing of such species should be based on the best scientific data available. Additionally, it included a provision that allowed groups or individuals to petition the government to list or de-list a species. If the petition contained reasonable support, the agency had to respond to it.

The law created two levels of concern: endangered and threatened. An endangered species was "in danger of extinction throughout all or a significant portion of its range." A threatened species was "likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range." Also, the species did not have to face worldwide extinction before it could be listed. No taking of any kind was allowed for endangered species; limited taking could be allowed for threatened species. Thus, the distinction between "endangered" and "threatened" species allowed for some flexibility in the program.

The 1973 Act divided jurisdiction of the program between the FWS and the National Marine Fisheries Service (NMFS), an agency of the **National Oceanic and Atmospheric Administration** in the Department of Commerce. The NMFS would have responsibility for species that were primarily marine; responsibility for marine mammals (**whales**, **dolphins**, etc.) was shared by the two agencies. The law also provided for the establishment of cooperative agreements between the federal government and the states on endangered species protection. This has not proved very successful due to a lack of funds to entice the states to participate and due to frequent conflict between the states (favoring development and **hunting**) and the FWS.

The most controversial aspect of the Act was Section 7, which required that no action by a federal agency, such as the destruction of critical **habitat**, jeopardize any endangered species. So, before undertaking, funding, or granting a permit for a project, federal agencies had to consult with the FWS as to the effect the action might have on endangered species. This provision proved to have enormous consequences, as many federal developments could be halted due to their affect on endangered species. The most famous and controversial application of this provision involved the **snail darter** and **Tellico Dam** in Tennessee. The **Tennessee Valley Authority** (TVA) was building the nearly completed dam when the snail darter was listed as endangered. Its only known habitat would be destroyed if the dam was completed. The TVA challenged the FWS evidence, but the TVA was itself soon challenged in the courts by environmentalists. In a case that was appealed through the Supreme Court, *TVA v. Hill*, the courts ruled that the ESA was clear: no federal action could take place that would jeopardize an endangered species. The dam could not be completed.

In response to the conflicts that followed the passage of the ESA, especially the swelling estimates of the number of endangered species and the snail darter-Tellico Dam issue, the 1978 re-authorization of the ESA included heated debate and a few significant changes in the law. Perhaps the most important change was the creation of the Endangered Species Committee, sometimes referred to as the "God Committee." Created in response to the snail darter controversy and the *TVA v. Hill* decision, this committee could approve federal projects that were blocked due to their harmful effects on endangered species. If an agency's actions were blocked due to an endangered species, they could appeal to this

committee for an exemption from the ESA. The committee, which consists of three cabinet secretaries, the administrators of the EPA and NOAA, the chair of the Council of Economic Advisors, and the governor from the state in which the project is located, weigh the advantages and disadvantages of the project and then make a decision as to the appeal. Ironically, the committee heard the appeal for Tellico Dam and rejected it. The committee has only been used three times, and only once, regarding the northern spotted owl and 1,700 acres (689 ha) of land in Oregon, has it approved an appeal. Nonetheless, the creation of the "God Committee" demonstrated that values beyond species survival had to be weighed into the endangered species equation.

Additionally, the 1978 amendments mandated: increased public participation and hearings when species were proposed for listing; a five-year review of all species on the list (to determine if any had improved to the point that they could be removed from the list); a requirement that the critical habitat of a species must be specified at the time the species is listed and that an economic assessment of the critical habitat designation must be done; the mandatory development of a recovery plan for each listed species; and a time limit between when a species was proposed for listing and when the final rule listing the species must be issued. These amendments were designed to do two things: to provide a loophole for projects that might be halted by the ESA and to speed up the listing process. Despite this latter goal, the many new requirements included in the amendments led to a further slowing of the listing process. It should also be noted that these amendments passed with overwhelming majorities in both the House and the Senate; there was still strong support for protecting endangered species, at least in the abstract, in Congress.

The 1982 re-authorization of the ESA did not lead to significant changes in the Act. The law was to have been re-authorized again in 1985, but opposition in the Senate prevented re-authorization until 1988. This demonstrated the growing uneasiness in Congress to the economic repercussions of the ESA. In addition to re-authorizing spending to implement the ESA through 1992, the 1988 amendments also increased the procedural requirements for recovery plans. This further underscored the tension between the desire for public participation at all stages of ESA implementation and the need for the government to move quickly to protect endangered species. Overall, the implementation of the ESA has not been successful. The law has suffered from two main problems: poor administrative capacity and fragmentation. The FWS has suffered from its lack of stature within the bureaucracy, its conflicting institutional mission, a severe lack of funds and personnel, and limited public support. Species assigned to the NMFS have fared even worse, as the agency has shown little interest in the ESA. Fragmentation is demonstrated with the division of responsibilities between the FWS and NMFS, the conflict with other federal agencies due to Section 7, and the federal-state conflicts over jurisdictional responsibility.

Endemic species

Endemic **species** are plants and animals that exist only in one geographic region. Species can be endemic to large or small areas of the earth: some are endemic to a particular continent, some to part of a continent, and others to a single island. Usually an area that contains endemic species is isolated in some way, so that species have difficulty spreading to other areas, or it has unusual environmental characteristics to which endemic species are uniquely adapted. Endemism, or the occurrence of endemic animals and plants, is more common in some regions than in others. In isolated environments such as the **Hawaiian Islands**, **Australia**, and the southern tip of Africa, as many of 90% of naturally occurring species are endemic. In less isolated regions, including Europe and much of North America, the%age of endemic species can be very small.

Biologists who study endemism do not only consider species, the narrowest classification of living things; they also look at higher level classifications of genus, family, and order. These hierarchical classifications are nested so that, in most cases, an order of plants or animals contains a number of families, each of these families includes several genera (plural of "genus"), and each genus has a number of species. These levels of classification are known as "taxonomic" levels.

Species is the narrowest taxonomic classification, with each species closely adapted to its particular **environment**. Therefore species are often endemic to small areas and local environmental conditions. Genera, a broader class, are usually endemic to larger regions. Families and orders more often spread across continents. As an example, the order Rodentia, or rodents, occurs throughout the world. Within this order, the family Heteromyidae occurs only in western North America and the northern edge of South America.

One member of this family, the genus *Dipodomys*, or kangaroo rats, is restricted to several western states and part of Mexico. Finally, the species *Dipodomys ingens*, occurs only in a small portion of the California coast. Most often endemism is considered on the lowest taxonomic levels of genus and species.

Animals and plants can become endemic in two general ways. Some evolve in a particular place, adapting to the local environment and continuing to live within the confines of that environment. This type of endemism is known as "autochthonous," or native to the place where it is found. An "allochthonous" endemic species, by contrast, originated somewhere else but has lost most of its earlier geographic range. A familiar autochthonous endemic species is the Australian koala, which evolved in its current environment and continues to occur nowhere else. A well-known example of allochthonous endemism is the California coast redwood (*Sequoia sempervirens*), which millions of years ago ranged across North America and Eurasia, but today exists only in isolated patches near the coast of northern California. Another simpler term for allochthonous endemics is "relict," meaning something that is left behind.

In addition to geographic relicts, plants or animals that have greatly restricted ranges today, there are what is known as "taxonomic relicts." These are species or genera that are sole survivors of once-diverse families or orders. **Elephants** are taxonomic relicts: millions of years ago the family Elephantidae had 25 different species (including woolly mammoths) in five genera. Today only two species remain, one living in Africa (*Loxodonta africana*) and the other in Asia (*Elephas maximus*). Horses are another familiar species whose family once had many more branches. Ten million years ago North America alone had at least 10 genera of horses. Today only a few Eurasian and African species remain, including the zebra and the ass. Common horses, all members of the species *Equus caballus*, returned to the New World only with the arrival of Spanish conquistadors.

Taxonomic relicts are often simultaneously geographic relicts. The ginkgo tree, for example was one of many related species that ranged across Asia 100 million years ago. Today the family Ginkgoales contains only one genus, *Ginkgo*, with a single species, *Ginkgo biloba*, that occurs naturally in only a small portion of eastern China. Similarly the coelacanth, a rare fish found only in deep waters of the Indian Ocean near **Madagascar**, is the sole remnant of a large and widespread group that flourished hundreds of millions of years ago.

Where living things become relict endemics, some sort of environmental change is usually involved. The redwood, the elephant, the ginkgo, and the coelacanth all originated in the Mesozoic era, 245–65 million years ago, when the earth was much warmer and wetter than it is today. All of these species managed to survive catastrophic environmental change that occurred at the end of the Cretaceous period, changes that eliminated dinosaurs and many other terrestrial and aquatic animals and plants. The end of the Cretaceous was only one of many periods of dramatic change; more recently two million years of cold ice ages and warmer interglacial periods in the Pleistocene substantially altered the distribution of the world's plants and animals. Species that survive such events to become relicts do so by adapting to new conditions or by retreating to isolated refuges where habitable environmental conditions remain.

When endemics evolve in place, isolation is a contributing factor. A species or genus that finds itself on a remote island can evolve to take advantage of local food sources or environmental conditions, or its characteristics may simply drift away from those of related species because of a lack of contact and interbreeding. Darwin's Galapagos finches, for instance, are isolated on small islands, and on each island a unique species of finch has evolved. Each finch is now endemic to the island on which it evolved. Expanses of water isolated these evolving finch species, but other sharp environmental gradients can contribute to endemism, as well. The humid southern tip of Africa, an area known as the Cape region, has one of the richest plant communities in the world. A full 90% of the Cape's 18,500 plant species occur nowhere else. Separated from similar **habitat** for millions of years by an expanse of dry **grasslands** and **desert**, local families and genera have divided and specialized to exploit unique local niches. Endemic speciation, or the **evolution** of locally unique species, has also been important in Australia, where 32% of genera and 75% of species are endemic. Because of its long isolation, Australia even has family-level endemism, with 40 families and sub-families found only on Australia and a few nearby islands.

Especially high rates of endemism are found on long-isolated islands, such as St. Helena, New Caledonia, and the Hawaiian chain. St. Helena, a volcanic island near the middle of the Atlantic, has only 60 native plant species, but 50 of these exist nowhere else. Because of the island's distance from any other landmass, few plants have managed to reach or colonize St. Helena. Speciation among those that have reached the remote island has since increased the number of local species. Similarly Hawaii and its neighboring volcanic islands, colonized millions of years ago by a relatively small number of plants and animals, now has a wealth of locally-evolved species, genera, and sub-families. Today's 1,200–1,300 native Hawaiian plants derive from about 270 successful colonists; 300–400 arthropods that survived the journey to these remote islands have produced over 6,000 descendent species today. Ninety-five percent of the archipelago's native species are endemic, including all ground birds. New Caledonia, an island midway between Australia and Fiji, consists partly of continental rock, suggesting that

at one time the island was attached to a larger landmass and its resident species had contact with those of the mainland. Nevertheless, because of long isolation 95% of native animals and plants are endemic to New Caledonia.

Ancient, deep lakes are like islands because they can retain a stable and isolated habitat for millions of years. Siberia's **Lake Baikal** and East Africa's Lake Tanganyika are two notable examples. Lake Tanganyika occupies a portion of the African Rift Valley, 0.9 mi (1.5 km) deep and perhaps 6 million years old. Fifty percent% of the lake's snail species are endemic, and most of its fish are only distantly related to the fish of nearby Lake Nyasa. Siberia's Lake Baikal, another rift valley lake, is 25 million years old and 1 mi (1.6 km) deep. Eighty-four percent of the lake's 2,700 plants and animals are endemic, including the nerpa, the world's only freshwater seal.

Because endemic animals and plants by definition have limited geographic ranges, they can be especially vulnerable to human invasion and habitat destruction. Island species are especially vulnerable because islands commonly lack large predators, and many island endemics evolved without defenses against predation. Cats, dogs, and other carnivores introduced by sailors have decimated many island endemics. The **flora** and **fauna** of Hawaii, exceptionally rich before Polynesians arrived with pigs, rats, and agriculture, were severely depleted because their range was limited and they had nowhere to retreat as human settlement advanced. Tropical rain forests, with extraordinary species diversity and high rates of endemism, are also vulnerable to human invasion. Many of the species eliminated daily in Amazonian rain forests are locally endemic, so that their entire range can be eliminated in a short time.

Endocrine disruptors

In recent years, scientists have proposed that **chemicals** released into the **environment** may be disrupting the endocrine system of humans and **wildlife**. The endocrine system is a network of glands and hormones that regulates many of the body's functions, such as growth, development, behavior, and maturation. The endocrine glands include the pituitary, thyroid, adrenal, thymus, pancreas, and the male and female gonads (testes and ovaries). These glands secrete regulated amounts of hormones into the bloodstream, where they act as chemical messengers as they are carried throughout the body to control and regulate many the body's functions. The hormones bind to specific cell sites called receptors. By binding to the receptors, the hormones trigger various responses in the tissues that contain the receptors.

An endocrine disruptor is an external agent that interferes in some way with the role of the hormones in the body. The agent might disrupt the endocrine system by affecting any of the stages of hormone production and activity, such as preventing the synthesis of a hormone, directly binding to hormone receptors, or interfering with the breakdown of a natural hormone. Disruption in endocrine function during highly sensitive prenatal periods is especially critical, as small changes in endocrine functions may have delayed consequences that may become evident later in adult life or in a subsequent generation. Adverse effects that might be a result of endocrine disruption include the development of cancers, reproductive and developmental effects, neurological effects (effects on behavior, learning and memory, sensory function, and psychomotor development), and immunological effects (immunosuppression, with resulting disease susceptibility).

Exposure to suspected endocrine disruptors may occur through direct contact with the chemicals or through ingestion of contaminated water, food, or air. Suspected endocrine disruptors can enter air or water from chemical and manufacturing processes and through **incineration** of products. Industrial workers may be exposed in work settings. Documented examples of health effects of humans exposed to endocrine disrupting chemicals include shortened penises in the sons of women exposed to dioxin-contaminated rice oil in China and reduced sperm count in workers exposed to high doses of **Kepone** in a Virginia **pesticide** factory. Diethylstilbestrol (DES), a synthetic estrogen, was used in the 1950s and 1960s by pregnant women to prevent miscarriages. Unfortunately it did not prevent miscarriages, but the teenage daughters of women who had taken DES suffered high rates of vaginal cancers, **birth defects** of the uterus and ovaries, and immune system suppression. These health effects were traced to their mothers' use of DES.

A variety of chemicals, including some pesticides, have been shown to result in endocrine disruption in animal laboratory studies. However, except for the incidences of endocrine disruption due to chemical exposures in the workplace and to the use of DES, causal relationships between exposure to specific environmental agents and adverse health effects in humans due to endocrine disruption have not yet been firmly established.

There is more evidence that the endocrine systems of fish and wildlife have been affected by chemical contamination in their habitats. Groups of animals that have been affected by endocrine disruption include snails, oysters, fish, alligators and other reptiles, and birds, including gulls and eagles. Whether effects on individuals of a particular **species** impact populations of that organism is difficult to prove. Whether endocrine disruption is confined to specific areas or is more widespread is also not known. In addition, proving that a specific chemical causes a particular endocrine effect is difficult, as animals are exposed to a variety of chemicals and non-chemical stressors. However, some persistent organic chemicals such as DDT (dichlorodiphenyltrichloroethane), PCBs (**polychlorinated biphenyls**), **dioxin**, and some pesticides have been shown to act as endocrine disruptors in the environment. Adverse effects seen that may be caused by endocrine disrupting mechanisms include abnormal thyroid function and development in fish and birds, decreased fertility in shellfish, fish, birds, and mammals, decreased hatching success in fish, birds, and reptiles, demasculinization and feminization of fish, birds, reptiles, and mammals, defeminization and masculinization of **gastropods**, fish, and birds, and alteration of immune and behavioral function in birds and mammals. Many potential endocrine disrupting chemicals are persistent and bioaccumulate in fatty tissues of organisms and increase in concentration as they move up through the food web. Because of this persistence and mobility, they can accumulate and harm organisms far from their original source.

More information is needed to define the ecological and human health risks of endocrine disrupting chemicals. Epidemiological investigations, exposure assessments, and laboratory testing studies for a wide variety of both naturally occurring and synthetic chemicals are tools that are being used to determine whether these chemicals as environmental contaminants have the potential to disrupt hormonally mediated processes in humans and animals.

Energy and the environment

Energy is a prime factor in environmental quality. Extraction, processing, shipping, and **combustion** of **coal**, oil, and **natural gas** are the largest sources of air pollutants, thermal and chemical **pollution** of surface waters, accumulation of mine **tailings** and toxic ash, and land degradation caused by **surface mining** in the United States.

On the other hand, a cheap, inexhaustible source of energy would allow us people to eliminate or repair much of the environmental damage done already and to improve the quality of the **environment** in many ways. Often, the main barrier to reclaiming degraded land, cleaning up polluted water, destroying wastes, restoring damaged ecosystems, or remedying most other environmental problems is that solutions are expensive—and much of that expense is energy costs. Given a clean, sustainable, environmentally benign energy source, people could create a true utopia and extend its benefits to everyone.

Our ability to use external energy to do useful work is one of the main characteristics that distinguishes humans from other animals. Clearly, technological advances based on this ability have made our lives much more comfortable and convenient than that of our early ancestors. They have also allowed us to make bigger mistakes, faster than ever before. A large part of our current environmental crisis is that our ability to modify our environment has outpaced our capacity to use energy and technology wisely.

In the United States, **fossil fuels** supply about 85% of the commercial energy. This situation cannot continue for very long because the supplies of these fuels are limited and their environmental effects are unacceptable. Americans now get more than half of their oil from foreign sources at great economic and political costs. At current rates of use,

known, economically extractable world supplies of oil and natural gas will probably last only a century or so. Reserves of coal are much larger, but coal is the dirtiest of all fuels. Its contribution of **greenhouse gases** that cause global warming are reason enough to curtail our coal use. In addition, coal burning is the largest single source in the United States of **sulfur dioxide** and **nitrogen oxides** (which cause respiratory health problems, **ecosystem** damage, and **acid** precipitation). Paradoxically, coal-burning **power plants** also release **radioactivity**, since radioactive minerals such as **uranium** and thorium are often present in low concentrations in coal deposits.

Nuclear power was once thought to be an attractive alternative to fossil fuels. Billed as "the clean energy alternative" and as an energy source "too cheap to bother metering," nuclear power was promoted in the 1960s as the energy source for the future. The disastrous consequences of accidents in nuclear plants, such as the explosion and fire at Chernobyl in the Ukraine in 1986, problems with releases of radioactive materials in mining and processing of fuels, and the inability to find a safe, acceptable permanent storage of nuclear waste have made nuclear power seem much less attractive in recent years. Between seventy and ninety percent of the citizens of most European and North American countries now regard nuclear power as unacceptable.

The United States Government once projected that 1,500 nuclear plants would be built. In 2002, only 105 plants were in operation and no new construction has been undertaken since 1975. Many of these aging plants are now reaching the end of their useful life. There will be enormous costs and technical difficulties in dismantling them and disposing of the radioactive debris. Some reactor designs are inherently safer than those now in operation, but public confidence in nuclear power technology is at such a low level that it seems unlikely that it will never supply much energy. Damming rivers to create hydroelectric power from spinning water turbines has the attraction of providing a low-cost, renewable, air pollution-free energy source. Only a few locations remain in the United States, however, where large hydroelectric projects are feasible. Many more sites are available in Canada, Brazil, India, and other countries, but the social and ecological effects of building large **dams**, **flooding** valuable river valleys, and eliminating free-flowing rivers are such that opposition is mounting to this energy source.

An example of the ecological and human damage done by large hydroelectric projects is seen in the James Bay region of Eastern Quebec. A series of huge dams and artificial lakes have flooded thousands of square miles of forest. **Migration** routes of caribou are disrupted, the **habitat** for game on which indigenous people depended is destroyed, and decaying vegetation has acidified waters, releasing **mercury** from the bedrock and raising mercury concentrations in fish to toxic levels. The **hunting** and gathering way of life of local Cree and Inuit people has probably been destroyed forever. This kind of tragedy has been repeated many times around the world by ill-conceived hydro projects.

There are several sustainable, environmentally benign energy sources that should be developed. Among these are wind power, **biomass** (burning **renewable energy** crops such as fast-growing trees or shrubs), small-scale hydropower (low head or run-of-the- river turbines), passive-solar space heating, active-solar water heaters, photovoltaic energy (direct conversion of sunlight to electricity), and ocean tidal or **wave power**. There may be unwanted environmental consequences of some of these sources as well, but they seem much better in aggregate than current energy sources. A big disadvantage is that most of these **alternative energy sources** are diffuse and not always available when or where we want to use energy.

We need ways to store and ship energy generated from these sources. There have been many suggestions that a breakthrough in battery technology could be on the **horizon**. Other possibilities include converting biomass into **methane** or **methanol** fuels or using electricity to generate **hydrogen** gas through electrolysis of water. These fuels would be easily storable, transportable, and used with current technology without great alterations of existing systems. It is estimated that some combination of these sustainable energy sources could supply all of American energy needs by utilizing only a small fraction (perhaps less than one percent) of United States land area. If means are available to move this energy efficiently, these energy farms could be in remote locations with little other value.

Clearly, the best way to protect the environment from damage associated with energy production is to use energy more efficiently. Many experts estimate that people could enjoy the same comfort and convenience but use only half as much energy if they practiced **energy conservation** using currently available technology. This would not require great sacrifices economically or in one's lifestyle. *See also* Acid rain; Air pollution; Greenhouse effect; Photovoltaic cell; Solar energy; Thermal pollution; Wind energy

Energy conservation

Energy **conservation** was a concept largely unfamiliar to America—and to much of the rest of the world—prior to 1973. Certainly some thinkers prior to that date thought about, wrote about, and advocated a more judicious use of the world's energy supplies. But in a practical sense, it seemed that the world's supply of **coal**, oil, and **natural gas** was virtually unlimited.

In 1973, however, the **Organization of Petroleum Exporting Countries** (OPEC) placed an arbitrary limit on the amount of **petroleum** that non-producing nations could buy from them. Although the OPEC embargo lasted only a short time, the nations of the world were suddenly forced to consider the possibility that they might have to survive on a reduced and ultimately finite supply of the **fossil fuels**.

In the United States, the OPEC embargo set off a flurry of administrative and legislative activity, designed to ensure a dependable supply of energy for the nation's further needs. Out of this activity came acts such as the **Energy Policy** and Conservation Act of 1976, the Energy Conservation and Production Act of 1976, and the National Energy Act of 1978.

An important feature of the nation's (and the world's) new outlook on energy was the realization of how much energy is wasted in **transportation**, residential and commercial buildings, and industry. When energy supplies appeared to be without limit, waste was a matter of small concern. However, when energy shortages began to be a possibility, conservation of energy sources assumed a high priority.

Energy conservation is certainly one of the most attainable goals the federal government can set for the United States. Almost every way we use energy results in enormous waste. Only about 20% of the energy content of **gasoline**, for example, is actually put to productive work in an **automobile**. Each time we make use of electricity, we produce waste when coal is burned to heat water to drive a turbine to operate a generator to make electricity. No wonder more than ninety% of the energy generated in the electrical process is wasted.

Fortunately, a vast array of conservation techniques are available in each of the major categories of energy use: transportation, residential and commercial buildings, and industry. In the area of transportation, conservation efforts focus on the nation's use of the private automobile for most personal travel. Certainly, the private automobile is an enormously wasteful method for moving people from one place to another. It is hardly surprising, therefore, that conservationists have long argued for the development of alternative means of transportation: bicycles, motorcycles, mopeds, carpools and van-pools, dial-a-rides, and various forms of **mass transit**. The amount of energy needed to move a single individual on the average is about one-third on a bus what it is in a private car. One need only compare the relative energy cost per passenger for eight people travelling in a commuter van-pool to the cost for a single individual in her private automobile to see the advantages of some form of mass transit.

For a number of reasons, however, mass transit systems in the United States are not very popular. While the number of new cars sold continues to rise year after year, investment in and use of heavy and light rail systems, trolley systems, subways and various types of pools remain modest.

Many authorities believe that the best hope for energy conservation in the field of transportation is to make private automobiles more efficient or to increase the tax on their use. Some experts argue that technology already exists for the construction of 100-mi-per-gal (42.5 km/l) automobiles if industry will make use of that technology. They also argue for additional research on electric cars as an energy-saving and pollution-reducing alternative to internal **combustion** vehicles.

Increasing the cost of using private automobiles has also been explored. One approach is to raise the tax on gasoline to a point where commuters begin to consider mass transit as an economical alternative. Increased parking fees and more aggressive traffic enforcement have also been tried. Such approaches often fail—or are never attempted—because public officials are reluctant to anger voters.

Other methods that have been suggested for increasing **energy efficiency** in automobiles include the design and construction of smaller, lighter cars, extending the useful life of a car, improving the design of cars and tires, and encouraging the design of more efficient cars through federal grants or tax credits.

A number of techniques are well known and could be used, however, to conserve energy in large buildings or even small two-room cottages. A thorough insulation of floors, walls, and ceilings, for example, can save up to 80% of the cost of heating and cooling a building.

In addition, buildings can be designed and constructed to take advantage of natural heating and cooling factors in the **environment**. A home in Canada, for example, should be oriented with windows tilting toward the south so as to take advantage of the sun's heating rays. A home in Mexico might have quite a different orientation.

One of the most extreme examples of environmental-friendly buildings are those that have been constructed at least partially underground. The earthen walls of these buildings provide a natural cooling effect in the summer and provide excellent insulation during the winter.

The kind, number, and placement of trees around a building can also contribute to energy efficiency. Trees that

lose their leaves in the winter will allow sunlight to heat a building during the coldest months, but will shield the building from the sun during the hot summer months.

Energy can also be conserved by modifying appliances used within a building. Prior to 1973, consumers became enamored with all kinds of electrical devices, from electric toothbrushes to electric shoe-shine machines to trash compactors. As convenient as these appliances may be, they are energy wasteful and do not always meet a basic human need.

Even items as simple as light bulbs can become a factor in energy conservation programs. Fluorescent light bulbs use at least 75% less energy than do incandescent bulbs, and they often last 20 times longer. Although many commercial buildings now use fluorescent lighting exclusively, it still tends to be relatively less popular in private homes.

As the largest single user of energy in American society, industry is a prime candidate for conservation measures. Always sensitive to possible money-saving changes, industry has begun to develop and implement energy savings devices and procedures. One such idea is **cogeneration**, the use of waste heat from an industrial process for use in the generation of electricity.

Another approach is the expanded use of **recycling** by industry. In many cases, re-using a material requires less energy than producing it from raw materials. Finally, researchers are continually testing new designs for equipment that will allow that equipment to operate on less energy.

Governments and utilities have two primary methods by which they can encourage energy conservation. One approach is to penalize individuals and companies that use too much energy. For example, an industry that uses large amounts of electricity might be charged at a higher rate per kilowatt hour than one that uses less electricity, a policy just the opposite of that now in practice in most places.

A more positive approach is to encourage energy conservation by techniques such as tax credits. Those who insulate their homes might, for example, be given cash bonuses by the local utility or a tax deduction by state or federal government.

In recent years, another side of energy conservation has come to the fore, its environmental advantages. Obviously, the less coal, oil, and natural gas that humans use, the fewer pollutants are released into the environment. Thus, a practice that is energy-wise, conservation, can also provide environmental benefits. Those concerned with global warming and **climate** change have been especially active in this area. They point out that reducing our use of fossil fuels will both reduce our consumption of energy and our release of **carbon dioxide** to the **atmosphere**. We can take a step toward heading off climate change, they point out, by taking the wise step of wasting less energy.

Energy conservation does not yet appear to have won the heart of most Americans. The general public concern about energy waste engendered by the 1973 OPEC **oil embargo** eventually dissolved into complacency. To be sure, some of the sensitivity to energy conservation created by that event has not been lost. Many people have switched to more energy-efficient forms of transportation, think more carefully about leaving house lights on all night, and take energy efficiency into consideration when buying major appliances.

But some of the more aggressive efforts to conserve energy have become stalled. Higher taxes on gasoline, for example, still are certain to raise an enormous uproar among the populace. And energy-saving construction steps that might well be mandated by law still remain optional, and frequently ignored.

In an era of apparently renewed confidence in an endless supply of fossil fuels, many people are no longer convinced that energy conservation is very important or have the will to act on their suspicion that it is. And governments, reflecting the will of the people, do not take leadership action to change that trend.

Energy efficiency

The utilization of energy for human purposes is a defining characteristic of industrial society. The conversion of energy from one form to another and the efficient production of mechanical work for heat energy has been studied and improved for centuries. The science of thermodynamics deals with the relationship between heat and work and is based on two fundamental laws of **nature**, the first and second **laws of thermodynamics**. The utilization of energy and the **conservation** of critical, nonrenewable energy resources are controlled by these laws and the technological improvements in the design of energy systems.

The First Law of Thermodynamics states the principle of conservation of energy: energy can be neither created nor

destroyed by ordinary chemical or physical means, but it can be converted from one form to another. Stated another way, *in a closed system, the total amount of energy is constant.* An interesting example of energy conversion is the incandescent light bulb. In the incandescent light bulb, electrical energy is used to heat a wire (the bulb filament) until it is hot enough to glow. The bulb works satisfactorily except that the great majority (95%) of the electrical energy supplied to the bulb is converted to heat rather than light. The incandescent bulb is not very efficient as a source of light. In contrast, a fluorescent bulb uses electrical energy to excite atoms in a gas, causing them to give off light in the process at least four times more efficiently than the incandescent bulb. Both light sources, however, conform to the First Law in that no energy is lost and the total amount of heat and light energy produced is equal to the amount of electrical energy flowing to the bulb.

The Second Law of Thermodynamics states that whenever heat is used to do work, some heat is lost to the surrounding **environment**. The complete conversion of heat into work is not possible. This is not the result of inefficient engineering design or implementation but, rather, a fundamental and theoretical thermodynamic limitation. The maximum, theoretically possible efficiency for converting heat into work depends solely on the operating temperatures of the heat engine and is given by the equations: $E = 1 - T_2/T_1$. T_1 is the absolute temperature at which heat energy is supplied and T_2 is the absolute temperature at which heat energy is exhausted.

The maximum possible thermodynamic efficiency of a four-cycle internal **combustion** engine is about 54%; for a diesel engine, the limit is about 56%; and for a steam engine, the limit is about 32%. The actual efficiency of real engines, which suffer from mechanical inefficiencies and parasitic losses (eg. friction, drag, etc.) is significantly lower than these levels. Although thermodynamic principles limit maximum efficiency, substantial improvements in energy utilization can be obtained through further development of existing equipment such as **power plants**, refrigerators, and automobiles and the development of new energy sources such as solar and geothermal.

Experts have estimated the efficiency of other common energy systems. The most efficient of these appear to be electric power generating plants (33% efficient) and steel plants (23% efficient). Among the least efficient systems are those for heating water (1.5–3%), for heating homes and buildings (2.5–9%), and refrigeration and air-conditioning systems (4–5%). It has been estimated that about 85% of the energy available in the United States is lost due to inefficiency.

The predominance of low efficiency systems reflects the fact that such systems were invented and developed when energy costs were low and there was little customer demand for energy efficiency. It made more sense then to build appliances that were inexpensive rather than efficient because the cost to operate them was so low. Since the 1973 **oil embargo** by the **Organization of Petroleum Exporting Countries** (OPEC), that philosophy has been carefully re-examined. Experts began to point out that more expensive appliances could be designed and built if they were also more efficient. The additional cost to the manufacturer, industry and homeowner could usually be recovered within a few years because of the savings in fuel costs.

The concept of energy efficiency suggests a new way of looking at energy systems and that is the examination of the total lifetime energy use and cost of the system. Consider the common light bulb. The total cost of using a light bulb includes both its initial price and the cost of operating it throughout its lifetime. When energy was cheap, this second factor was small. There was little motivation to make a bulb that was more efficient when the life-cycle savings for its operation was minimal.

But as the cost of energy rises, that argument no longer holds true. An inefficient light bulb costs more and more to operate as the cost of electricity rises. Eventually, it makes sense to invent and produce more efficient light bulbs. Even if these bulbs cost more to buy, they pay back that cost in long-term operating savings.

Thus, consumers might balk at spending $25 for a fluorescent light bulb unless they knew that the bulb would last ten times as long as an incandescent bulb that costs $3.75. Similar arguments can and have been used to justify the higher initial cost of energy-saving refrigerators, solar-heating systems, household insulation, improved internal combustion engines and other energy-efficient systems and appliances.

Governmental agencies, utilities, and industries are gradually beginning to appreciate the importance of increasing energy efficiency. The 1990 amendments to the **Clean Air Act** encourage industries and utilities to adopt more efficient equipment and procedures. Certain leaders in the energy field, such as Pacific Gas and Electric and Southern California Edison have already implemented significant energy efficiency programs.

Energy flow

Understanding energy flow is vital to many environmental issues. One can describe the way ecosystems function by saying that matter cycles and energy flows. This is based on the laws of **conservation** of matter and energy and the second law of thermodynamics, or the law of energy degradation.

Energy flow is strictly one way, such as from higher to lower or from hotter to colder. Objects cool only by loss of heat. All cooling units, such as refrigerators and air conditioners, are based on this principle: they are essentially heat pumps, absorbing heat in one place and expelling it to another.

This heat flow is explained by the laws of radiation, as seen in fire and the color wheel. All objects emit radiation, or heat loss, but the hotter the object the greater the amount of radiation, and the shorter and more energetic the wavelength. As energy intensities rise and wavelengths shorten, the radiation changes from infrared to red, then orange, yellow, green, blue, violet, and ultraviolet. A blue flame, for example, is desired for gas appliances. A well-developed wood fire is normally yellow, but as the fire dies out and cools, the color gradually changes to orange, then red, then black. Black coals may still be very hot, giving off invisible, infrared radiation. These varying wavelengths are the main differences seen in the electromagnetic spectrum.

All chemical reactions and **radioactivity** emit heat as a by-product. Because this heat radiates out from the source, the basis of the second law of thermodynamics, one can never achieve 100% **energy efficiency**. There will always be a heat-loss tax. One can slow down the rate of heat loss through insulating devices, but never stop it. As the insulators absorb heat, their temperatures rise and they in turn lose heat.

There are three main applications of energy flow to environmental concerns. First, only 10% of the food passed on up the **food chain/web** is retained as body mass; 90% flows to the **atmosphere** as heat. In terms of caloric efficiency, more calories are obtained by eating plant food than meat. Since fats are more likely to be part of the 10% retained as body mass, pesticides dissolved in fat are subject to **bioaccumulation** and **biomagnification**. This explains the high levels of DDT in birds of prey like the **peregrine falcon** (*Falco peregrinus*) and the **brown pelican** (*Pelecanus occidentalis*).

Second, the%age of waste heat is an indicator of energy efficiency. In light bulbs, 5% produces light and 95% heat, just the opposite of the highly efficient fire fly. Electrical generation from **fossil fuels** or **nuclear power** produces vast amounts of waste heat.

Third, control of heat flow is a key to comfortable indoor air and solving global warming. Well-insulated buildings retard heat flow, reducing energy use. Atmospheric **greenhouse gases**, such as **anthropogenic carbon dioxide** and **methane**, retard heat flow to space, which theoretically should cause global temperatures to rise. Policies that reduce these greenhouse gases allow a more natural flow of heat back to space. *See also* Greenhouse effect

Energy path, hard vs. soft

What will energy use patterns in the year 2100 look like? Such long-term predictions are difficult, risky, and perhaps impossible. Could an American citizen in 1860 have predicted what the pattern of today's energy use would be like?

Yet, there are reasons to believe that some dramatic changes in the ways we use energy may be in store over the next century. Most importantly, the world's supplies of nonrenewable energy—especially, **coal**, oil, and natural gas—continue to decrease. Critics have been warning for a least two decades that time was running out for the **fossil fuels** and that we could not count on using them as prolifically as we had in the past.

For at least two decades, experts have debated the best way to structure our energy use patterns in the future. The two most common themes have been described (originally by physicist Amory Lovins) as the "hard path" and the "soft path."

Proponents of the hard path argue essentially that we should continue to operate in the future as we have in the past, except more efficiently. They point out that predictions from the 1960s and 1970s that our oil supplies would be depleted by the end of the century have been proved wrong. If anything, our reserves of fossil fuels may actually have increased as economic incentives have encouraged further exploration.

Our energy future, the hard-pathers say, should focus on further incentives to develop conventional energy sources such as fossil fuels and **nuclear power**. Such incentives might include tax breaks and subsidies for coal, **uranium** and **petroleum** companies. When our supplies of fossil fuels do begin to be depleted, our emphasis should shift to a greater reliance on nuclear power.

An important feature of the hard energy path is the development of huge, centralized coal-fired and nuclear-powered plants for the generation of electricity. One characteristic of most hard energy proposals, in fact, is the emphasis on very large, expensive, centralized systems. For example, one would normally think of **solar energy** as a part of the soft energy path. But one proposal developed by the National Aeronautics and Space Administration (NASA) calls for a gigantic solar power station to be orbited around the earth. The station could then transmit power via microwaves to centrally-located transmission stations at various points in the earth's surface.

Those who favor a soft energy path have a completely different scenario in mind. Fossil fuels and nuclear power must diminish as sources of energy as soon as possible, they say. In their place, alternative sources of power such as hydropower, **geothermal energy**, **wind energy**, and photovoltaic cells must be developed.

In addition, the soft-pathers say, we should encourage **conservation** to extend coal, oil, and **natural gas** supplies as long as possible. Also since electricity is one of the most wasteful of all forms of energy, its use should be curtailed.

Most importantly, soft-path proponents maintain energy systems of the future should be designed for small-scale use. The development of more efficient solar cells, for example, would make it possible for individual facilities to generate a significant portion of the energy they need.

Underlying the debate between hard- and soft-pathers is a fundamental question as to how society should operate. On the one hand are those who favor the control of resources in the hands of a relatively small number of large corporations. On the other hand are those who prefer to have that control decentralized to individual communities, neighborhoods, and families. The choice made between these two competing philosophies will probably determine which energy path the United States and the world will ultimately follow. *See also* Alternative energy sources; Alternative fuels; Energy and the environment

Energy policy

Energy policies are the actions governments take to affect the demand for energy as well as the supply of it. These actions include the ways in which governments cope with energy supply disruptions and their efforts to influence energy consumption and economic growth.

The energy policies of the United States government have often worked at cross purposes, both stimulating and suppressing demand. Taxes are perhaps the most important kind of energy policy, and **energy taxes** are much lower in the U. S. than in other countries. This is partially responsible for the fact that energy consumption per capita is higher than elsewhere, and there is less incentive to invest in **conservation** or alternative technologies. Following the 1973 Arab **oil embargo**, the federal government instituted price controls which kept energy prices lower than they would otherwise have been, thereby stimulating consumption. Yet the government also instituted policies at the same time, such as fuel-economy standards for automobiles, which were designed to increase conservation and lower energy use. Thus, policies in the period after the embargo were contradictory: what one set of policies encouraged, the other discouraged.

The United States government has a long history of different types of interference in energy markets. The **Natural Gas** Act of 1938 gave the **Federal Power Commission** the right to control prices and limit new pipelines from entering the market. In 1954 The Supreme Court extended price controls to field production. Before 1970, the Texas Railroad Commission effectively controlled oil output (in the United States) through prorationing regulations that provided multiple owners with the rights to underground pools. The federal government provided tax breaks in the form of intangible drilling expenses and gave the oil companies a depletion allowance. A program was also in place from 1959 to 1973 which limited oil imports and protected domestic producers from cheap foreign oil. The ostensible purpose of this policy was maintaining national security, but it contributed to the depletion of national reserves.

After the oil embargo, Congress passed the Emergency **Petroleum** Allocation Act giving the federal government the right to allocate fuel in a time of shortage. In 1974 President Gerald Ford announced Project Independence which was designed to eliminate dependence on foreign imports. Congress passed the Federal Non-Nuclear Research and Development Act in 1974 to focus government efforts on non-nuclear research. Finally, in 1977 Congress approved the cabinet-level creation of the U. S. Department of Energy (DOE) which had a series of direct and indirect policy approaches at its disposal, designed to encourage and coerce both the energy industry as well as the commercial and residential sectors of the country to make changes. After

Ronald Reagan became president, many DOE programs were abolished, though DOE continued to exist, and the net impact has probably been to increase economic uncertainty.

Energy policy issues have always been very political in nature. Different segments of the energy industry have often been differently affected by policy changes, and various groups have long proposed divergent solutions. The energy crisis, however, intensified these conflicts. Advocates of strong government action called for policies which would alter consumption habits, reducing dependence on foreign oil and the nation's vulnerability to an oil embargo. They have been opposed by proponents of free markets, some of whom considered the government itself responsible for the crisis. Few issues were subject to such intensive scrutiny and fundamental conflicts over values as energy policies were during this period. Interest groups representing causes from **energy conservation** to **nuclear power** mobilized. Business interests also expanded their lobbying efforts.

An influential advocate of the period was Amory Lovins, who helped create the **renewable energy** movement. His book, *Soft Energy Paths: Toward A Durable Peace* (1977), argued that energy problems existed because large corporations and government bureaucracies had imposed expensive centralized technologies like nuclear power on society. Lovins argued that the solution was in small scale, dispersed, technologies. He believed that the "hard path" imposed by corporations and the government led to an authoritarian, militaristic society while the "soft path" of small-scale dispersed technologies would result in a diverse, peaceful, self-reliant society.

Because **coal** was so abundant, many in the 1970s considered it a solution to American dependence on foreign oil, but this expectation has proved to be mistaken. During the 1960s, the industry had been controlled by an alliance between management and the union, but this alliance disintegrated by the time of the energy crisis, and wildcat strikes hurt productivity. Productivity also declined because of the need to address safety problems following passage of the 1969 Coal Mine Health and Safety Act. Environmental issues also hurt the industry following passage of the **National Environmental Policy Act** of 1969, the **Clean Air Act** of 1970, the **Clean Water Act** of 1972, and the 1977 **Surface Mining Control and Reclamation Act**. Worker productivity in the mines dropped sharply from 19 tons per worker day to 14 tons, and this decreased the advantage coal had over other fuels. The 1974 Energy Supply and Environmental Coordination Act and the 1978 Fuel Use Act, which required utilities to switch to coal, had little effect on how coal was used because so few new plants were being built.

Other energy-consuming nations responded to the energy crises of 1973–74 and 1979–80 with policies that were different from the United States. Japan and France, although via different routes, made substantial progress in decreasing their dependence on Mideast oil. Great Britain was the only major industrialized nation to become completely self-sufficient in energy production, but this fact did not greatly aid its ailing economy. When energy prices declined and then stabilized in the 1980s, many consuming nations eliminated the conservation incentives they had put in place.

Japan is the most heavily petroleum-dependent industrialized nation. To pay for a high level of energy and raw material imports, Japan must export the goods which it produces. When energy prices increased after 1973, it was forced to expand exports. The rate of economic growth in Japan began to decline. Annual growth in GNP averaged nearly 10% from 1963–1973, and from 1973–1983 it was just under 4%, although the association between economic growth and energy consumption has weakened.

The Energy Rationalization Law of 1979 was the basis for Japan's energy conservation efforts, providing for the financing of conservation projects and a system of tax incentives. It has been estimated that over 5% of total Japanese national investment in 1980 was for energy-saving equipment. In the cement, steel, and chemical industries over 60% of total investment was for energy conservation, Japanese society shifted from petroleum to a reliance on other forms of energy including nuclear power and liquefied natural gas.

In France, energy resources at the time of the oil embargo were extremely limited. It possessed some natural gas, coal, and hydropower, but together these sources constituted only 0.7% of the world's total energy production. By 1973, French dependence on foreign energy had grown to 76.2%: oil made up 67% of the total energy used in France, up from 25% in 1960.

France had long been aware of its dependence on foreign energy and had taken steps to overcome it. Political instability in the Mideast and North Africa had led the government to take a leading role in the development of civilian nuclear power after World War II. In 1945 Charles de Gaulle set up the French **Atomic Energy Commission** to develop military and peaceful uses for nuclear power. The nuclear program proceeded at a very slow pace until the 1973 embargo, after which there was rapid growth in France's reliance on nuclear power. By 1990, more than 50 reactors had been constructed and over 70% of France's energy came from nuclear power. France now exports electricity to nearly all its neighbors, and its rates are about the lowest in Europe. Starting in 1976 the French government also subsidized 3,100 conservation projects at a cost of more than 8.4 billion francs, and these subsidies were particularly effective in encouraging energy conservation.

Concerned about oil supplies during World War I, the British government had taken a majority interest in British Petroleum and tried to play a leading role in the search for new oil. After the World War II, the government nationalized the coal, gas, and electricity industries, creating, for ideological reasons as well as for postwar reconstruction, the National Coal Board, British Gas Corporation, and Central Electricity Generating Board. After the discovery of oil reserves in the 1970s in the North Sea, the government established the British National Oil Company. This government corporation produced about 7% of North Sea oil and ultimately handled about 60% of the oil produced there.

All the energy sectors in the United Kingdom were thus either partially or completely nationalized. Government relations with the nationalized industries often were difficult, because the two sides had different interests. The government intervened to pursue macroeconomic objectives such as price restraint, and it attempted to stimulate investment at times of unemployment. The electric and gas industries had substantial operating profits and they could finance their capital requirements from their revenues, but profits in the coal industry were poor, the work force was unionized, and opposition to the closure of uneconomic mines was great. Decision-making was highly politicized in this nationalized industry, and the government had difficulty addressing the problems there. It was estimated that 90% of mining losses came from 30 of the 190 pits in Great Britain, but only since 1984–85 has there been rapid mine closure and enhanced productivity. New power-plant construction was also poorly managed, and comparable coal-fired power stations cost twice as much in Great Britain as in France or Italy.

The Conservative Party proposed that the nationalized energy industries be privatized. However, with the exception of coal, these energy industries had natural monopoly characteristics: economies of scale and the need to prevent duplicate investment in fixed infrastructure. The Conservative Party called for regulation after privatization to deal with the natural monopoly characteristics of these industries, and it took many steps toward privatization. In only one area, however, did it carry its program to completion, abolishing the British National Oil Company and transferring its assets to private companies. *See also* Alternative energy sources; Corporate Average Fuel Efficiency Standards; Economic growth and the environment; Electric utilities; Energy and the environment; Energy efficiency; Energy path, hard vs. soft

Energy recovery

A fundamental fact about energy use in modern society is that huge quantities are lost or wasted in almost every field and application. For example, the series of processes by which nuclear energy is used to heat a home with electricity results in a loss of about 85 percent of all the energy originally stored in the **uranium** used in the nuclear reactor. Industry, utilities, and individuals could use energy far more efficiently if they could find ways to recover and **reuse** the energy that is being lost or wasted.

One such approach is **cogeneration**, the use of waste heat for some useful purpose. For example, a factory might be redesigned so that the steam from its operations could be used to run a turbine and generate electricity. The electricity could then be used elsewhere in the factory or sold to power companies. Cogeneration in industry can result in savings of between 10 and 40 percent of energy that would otherwise be wasted.

Cogeneration can work in the opposite direction also. Hot water produced in a utility plant can be sold to industries that can use it for various processes. Proposals have been made to use the wasted heat from electricity plants to grow flowers and vegetables in greenhouses, to heat water for commercial fish and shell-fish farms, and to maintain warehouses at constant temperatures. The total **energy efficiency** resulting from this sharing is much greater than it would be if the utility's water was simply discarded.

Another possible method of recovering energy is by generating or capturing **natural gas** from **biomass**. For example, as organic materials decay naturally in a **landfill**, one of the products released is **methane**, the primary component of natural gas. Collecting methane from a landfill is a relatively simple procedure. Vertical holes are drilled into the landfill and porous pipes are sunk into the holes. Methane diffuses into the pipes and is drawn off by pumps. The recovery system at the Fresh Kills landfill on Staten Island, New York, for example, produces enough methane to heat 10,000 homes.

Biomass can also be treated in a variety of ways to produce methane and other combustible materials. Sewage, for example, can be subjected to **anaerobic digestion**, the primary product of which is methane. Pyrolysis is a process in which organic wastes are heated to high temperatures in the absence of oxygen. The products of this reaction are solid, liquid, and gaseous **hydrocarbons** whose composition is similar to those of **petroleum** and natural gas. Perhaps the most known example of this approach is the manufacture of **methanol** from biomass. When mixed with **gasoline**, a new fuel, **gasohol**, is obtained.

Energy can also be recovered from biomass simply by **combustion**. The waste materials left after sugar is extracted from sugar cane, known as *bagasse*, have long been used as

a fuel for the boilers in which the sugar extraction occurs. The burning of **garbage** has also been used as an energy source in a wide variety of applications such as the heating of homes in Sweden, the generation of electricity to run streetcars and subways in Milan, Italy, and the operation of a desalination plant in Hempstead, Long Island.

The recovery of energy that would otherwise be lost or wasted has a secondary benefit. In many cases, that wasted energy might cause **pollution** of the **environment**. For example, the wasted heat from an electric power plant may result in **thermal pollution** of a nearby waterway. Or the escape of methane into the **atmosphere** from a landfill could contribute to **air pollution**. Capture and recovery of the waste energy not only increases the efficiency with which energy is used, but may also reduce some pollution problems.

Energy Reorganization Act (1973)

Passed in 1974 during the Ford Administration, this act created the **Energy Research and Development Administration** (ERDA) and **Nuclear Regulatory Commission** (NRC). The purpose of the act was to begin an extensive non-nuclear federal research program, separating the regulation of the **nuclear power** from research functions. Regulation was carried out by the NRC, while nuclear power research was carried out by the ERDA. The passage of the 1974 Energy Reorganization Act ended the existence of the **Atomic Energy Commission**, which had been the main instrument to implement nuclear policy. In 1977 ERDA incorporated into the newly created **U.S. Department of Energy**. *See also* Alternative energy sources; Energy policy

Energy Research and Development Administration

This agency was created in 1974 from the non-regulatory parts of the **Atomic Energy Commission** (AEC), and it existed until 1977, when it was incorporated into the **U.S. Department of Energy**. In its short life span, the Energy Research and Development Administration (ERDA) started to diversify U.S. energy research outside of **nuclear power**. Large-scale demonstration projects were begun in numerous areas. These included projects to convert **coal** and solid wastes into liquid and gaseous fuels; experiments on methods to extract and process **oil shale** and **tar sands**, as well as an effort to develop a viable breeder reactor that would ensure a virtually inexhaustible source of **uranium** for electricity. The agency also supported research on **solar energy** for space heating, industrial process heat, and electricity. In the short time available, basic problems could not be solved, and the achievements of many of the demonstration projects were disappointing. Nevertheless, many important advances were made in commercializing cost-effective technologies for **energy conservation**, such as energy-efficient lighting systems, improved heat pumps, and better heating systems. The agency also conducted successful research in environmental, safety, and health areas.

Energy taxes

The main energy tax levied in the United States is the one on **petroleum**, though the United States tax is half of the amount levied in other major industrialized nations. As a result, **gasoline** prices in the United States are much lower than elsewhere, and both environmentalists and others have argued that this encourages energy consumption and **environmental degradation** and causes national and international security problems.

In 1993, the House passed a **Btu** tax while the Senate passed a more modest tax on **transportation** fuels. A Btu tax would restrict the burning of **coal** and other **fossil fuels** and proponents maintain that this would be both environmentally and economically beneficial. Every barrel of oil and every ton of coal that is burned adds **greenhouse gases** to the **atmosphere**, increasing the likelihood that **future generations** will face a global climatic calamity. United States dependence on foreign oil, much of it from potentially unstable nations like Iraq, now approaches 50%. A Btu tax would create incentives for **energy conservation**, and it would help stimulate the search for alternatives to oil. It would also help reduce the burgeoning trade deficit, of which foreign petroleum and petroleum-based products now constitute nearly 40%.

President Bill Clinton urged Americans to support higher energy taxes because of the considerable effect they could have on the federal budget deficit. For instance, if the government immediately raised gasoline prices to levels commonly found in other industrial nations (about $4.15 a gallon), the budget deficit would almost be eliminated. It is estimated that every penny increase in gasoline taxes, yields a billion dollars in revenue for the federal treasury, and in June 2002 the budget deficit was estimated to be about $6 trillion.

Of course, to raise gasoline taxes immediately to these levels is utterly impractical, as the effects on the economy would be catastrophic. It would devastate the economics of rural and western states. Inflation across the country would soar and job losses would skyrocket. Supporters of increasing energy taxes agree that the increases must be gradual and predictable, so people can adjust. Many believe they should take place over a 15 year period, after which energy prices in the United States would be roughly equivalent to those in other industrial nations.

Many economists emphasize that the positive effects of higher energy taxes will be felt only if there are no increases in government spending. It is, they believe, ultimately a question of how Americans want to be taxed. Do they want wages, profits, and savings to be taxed, as they are now, or their use of energy? In the former case, the government is taxing a desirable activity which should be encouraged for the sake of job creation and economic expansion. In the latter case, it is taxing undesirable activity which should be discouraged for the sake of protecting the **environment** and preserving national security. *See also* Energy policy; Environmental economics

Enteric bacteria

Enteric bacteria are defined as bacteria which reside in the intestines of animals. Members of the Enterobacteriaceae family, enteric bacteria are important because some of them symbiotically aid the digestion of their hosts, while other pathogenic **species** cause disease or death in their host organism. The pathogenic members of this family include species from the genera *Escherichia*, *Salmonella*, *Shigella*, *Klebsiella*, and *Yersinia*. All of these pathogens are closely associated with fecal contamination of foods and water. In North America, the reported incidence of salmonellosis outweighs the occurrence of all of the other reportable diseases by other enteric bacteria combined.

Most infections from enteric pathogens require large numbers of organisms to be ingested by immunocompetent adults, with the exception of *Shigella*. Symptoms include gastrointestinal distress and diarrhea. The enteric bacteria related to ***Escherichia coli*** are known as the ***coliform*** bacteria. Coliform bacteria are used as indicators of pathogenic enteric bacteria in drinking and recreational waters. *See also* Sewage treatment

Environment

When people say "I am concerned about the environment," what do they mean? What does the use of the definite article mean in such a statement? Is there such a thing as "the" environment?

Environment is derived from the French words *environ* or *environner*, meaning "around," which in turn originated from the Old French *virer* and *viron* (together with the prefix *en*), which mean "a circle, around, the country around, or circuit." Etymologists frequently conclude that, in English usage at least, *environment* is the total of the things or circumstances around an organism—including humans—though *environs* is limited to the "surrounding neighborhood of a specific place, the neighborhood or vicinity."

Even a brief etymological encounter with the word environment provokes two persuasive suggestions for possible structuring of a contemporary definition. First, the word environment is identified with a totality, the everything that encompasses each and all of us, and this association is established enough to be not lightly dismissed. The very notion of "environment," as Anatol Rapoport indicated, suggest the partitioning of a "portion of the world into regions, an inside and an outside." The environment is the outside. Second, the word's origin in the phrase "to environ" indicates a process derivative, one that alludes to some sort of action or interaction, at the very least inferring that the encompassing is active, in some sense reciprocal, that the environment, whatever its **nature**, is not simply an inert phenomenon to be impacted without response or without affecting the organism in return. Environment must be a relative word, because it always refers to something "environed" or enclosed.

Ecology as a discipline is focused on studying the interactions between an organism of some kind and its environment. So ecologists must be concerned with what H. L. Mason and J. H. Langenheim described as a "key concept in the structure of ecological knowledge," but a concept with which ecologists continue to have problems of confusion

between ideas and reality—the concept of environment. Mason and Langenheim's article "Language Analysis and the Concept Environment" continues to be the definitive statement on the use of the word environment in experimental ecology.

The results of Mason and Langenheim's analysis were essentially four-fold: 1) they limited environmental phenomena "in the universal sense" to only those phenomena that have an operational relation with any organism: other phenomena present that do not enter a reaction system are excluded, or dismissed as not "environmental phenomena"; 2) they restricted the word environment itself to mean "the class composed of the sum of those phenomena that enter a reaction system of the organism or otherwise directly impinge upon it" so that physical exchange or impingement becomes the clue to a new and limited definition; 3) they specifically note that their definition does not allude to the larger meaning implicit in the etymology of the word; and 4) they designate their limited concept as *operational environment* but state that when the word environment is used with qualification, then it still refers to the operational construct, establishing that "'environment' per se is synonymous with 'operational environment'."

This definition does allow a prescribed and limited conception of environment and might work for experimental ecology but is much too limited for general usage. Environmental phenomena of relevance to the aforementioned concern for "the" environment must incorporate a multitude of things other than those that physically impinge on each human being. And it is much more interactive and overlapping than a restricted definition would have people believe. To better understand contemporary human interrelationships with the world around them, environment must be an incorporative, holistic term and concept.

Thinking about the environment in the comprehensive sense—with the implication that *everything* is the environment with each entity connected to each of a multitude of others—makes environment what David Currie in a book of case studies and material on **pollution** described "as not a modest concept." But, such scope and complexity, difficult as they are to resolve, intensify rather than eliminate the very real need for a kind of transcendence. The assumption seems valid that human consciousness regarding environment needs to be raised, not restricted. Humans need increasingly to comprehend and care about what happens in far away places and to people they do not know but that do affect them, that do impact even their localized environments, that do impinge on their individual well-being. And they need to incorporate the reciprocal idea that their actions impact people and environments outside the immediate in place and time: in the world today, environmental impacts transcend the local. Thus it is necessary that human awareness of those impacts also be transcendent.

It is uncertain that confining the definition of environment to operationally narrow physical impingement could advance this goal. One suspects instead that it would significantly retard it, a retardation that contemporary human societies can ill afford. Internalization of a larger environment, including an understanding of common usages of the word, might on the other hand aid people in caring about, and assuming responsibility for, what happens to that environment and to the organisms in it.

An operational definition can help people find the mechanisms to deal with problems immediate and local, but can, if they are not careful, limit them to an unacceptable mechanistic and unfeeling approach to problems in the environment-at-large.

Acceptance of either end of the spectrum—a limited operational definition or an incorporative holistic definition—as the only definition creates more confusion than clarification. Both are needed. Outside the laboratory, however, in study of the interactional, interdependent world of contemporary humankind, the holistic definition must have a place. A sense of the comprehensive "out there," of the totality of world and people as a functionally significant, interacting unit should be seeping into the consciousness of every person.

Carefully chosen qualifiers can help deal with the complexity: "natural" or "built" or "perceptual" all specify aspects of human surroundings more descriptive and less incorporative than "environment" used alone, without adjectives. Other noun can also pick up some of the meanings of environment, though none are direct synonyms: **habitat**, milieu, mis en scence, ecumene all designate specified and limited aspects of the human environment, but none except "environment" are incorporative of the whole complexity of human surroundings.

An understanding of environment must not be limited to an abstract concept that relates to daily life only in terms of whether to recycle cans or walk to work. The environment is the base for all life, the source of all goods. Poor people in underdeveloped nations know this; their day-to-day survival depends on what happens in their local environments. Whether it rains or does not, whether commercial seiners move into local fishing grounds or leave them alone, and whether local forest products are lost to the cause of world timber production affect these people more directly. What they, like so many other humans around the world, may not also recognize, is that "environment" now extends far beyond the bounds of the local: environment is the intimate enclosure of the individual or a local human population *and* the global domain of the human **species**.

The Brundtland report ***Our Common Future*** recognized this with a healthy, modern definition: "The environment does not exist as a sphere separate from human actions, ambitions, and needs, and attempts to defend it in isolation from human concerns have given the word 'environment' a connotation of naivety in some political circles." The report goes on to note that "the 'environment' is where we all live...and 'development' is what we all do in attempting to improve our lot within that abode. The two are inseparable."

Each human being lives in a different environment than any other human because every single one screens their surroundings through their own individual experience and perceptions. Yet all human beings live in the same environment, an external reality that all share, draw sustenance from, and excrete into. So understanding environment becomes a dialectic, a resolution and synthesis of individual characteristics and shared conditions. Solving environmental problems depends on the intelligence exhibited in that resolution.

Environment Canada

Environment Canada is the agency with overall responsibility for the development and implementation of policies related to environmental protection, monitoring, and research within the government of Canada. Parts of this mandate are shared with other federal agencies, including those responsible for agriculture, forestry, fisheries, and **nonrenewable resources** such as minerals. Environment Canada also works with the environment-related agencies of Canada's 10 provincial and two territorial governments through such groups as the Canadian Council of Ministers of the Environment.

The head of Environment Canada is a minister of the federal cabinet, who is "responsible for policies and actions to preserve and enhance the quality of the environment for the benefit of present and **future generations** of Canadians."

In 1990, following a lengthy and extensive consultation process organized by Environment Canada, the Government of Canada released its *Canada's Green Plan for a Healthy Environment*, which details the broader goals, as well as many specific objectives, to be pursued towards achieving a state of ecologically sustainable economic development in Canada. The first and most general of the national objectives under the *Green Plan* is to "secure for current and future generations a safe and healthy environment, and a sound and prosperous economy."

The *Green Plan* is intended to set a broad environmental framework for all government activities and objectives, including the development of policies. The government of Canada has specifically committed to working toward the following priority objectives: (1) clean air, water, and land; (2) **sustainable development** of renewable resources; (3) protection of special places and **species**; (4) preserving the integrity of northern Canada; (5) global environmental security; (6) environmentally responsible decision making at all levels of society; and (7) minimizing the effects of environmental emergencies. Environment Canada will play the lead role in implementing the vision of the *Green Plan* and in coordinating the activities of the various agencies of the government of Canada.

In order to be able to integrate the dual challenges of a new environmental agenda (set by the expectations of Canadians in general and the federal government in particular) and the need to continue to deliver traditional programs, Environment Canada is moving from a three-program to a one-program administrative structure. Under that single program, six activities are coordinated: (1) the Atmospheric Environment Service activity, through which information is provided and research conducted on weather, **climate**, oceanic conditions, and **air quality**; (2) the Conservation and Protection Service activity, which focuses on special species and places, global environmental integrity, the integrity of Canadian ecosystems, environmental emergencies, and ecological and economic interdependence; (3) the **Canadian Parks Service** activity, concentrating on the ecological and cultural integrity of special places, as well as on environmental and cultural citizenship; (4) the Corporate Environmental Affairs activity, dealing with environmentally responsible decision making and ecosystem-science leadership; (5) the State of the Environment Reporting activity, through which credible and comprehensive environmental information, linked with socio-economic considerations, is provided to Canadians; and (6) the Administration activity, covering corporate management and services. *See also* Environment; Future generations

Environmental accounting

A system of national or business accounting where such environmental assets as air, water, and land are not considered to be free and abundant resources but instead are considered to be scarce economic assets. Any environmental damage caused by the production process must be treated as an economic expense and entered on the balance sheet accordingly. It is important to include in this framework the full environmental cost occurring over the full life cycle of a product, including not only the environmental costs incurred in the production process, but also the environmental costs resulting from use, **recycling** and disposal of products. This is also known as the cradle-to-grave approach. *See also* Ecological economics

Environmental aesthetics

In his journal, **Henry David Thoreau** asked in 1859 "In what book is this world and its beauty described? Who has plotted the steps toward the discovery of beauty?" Almost a 100 years later, in his book *The Sand County Almanac*, ecologist **Aldo Leopold** addressed Thoreau's question by advocating what he called a "conservation esthetic" as the door to appreciating the richness of the natural world, and a resulting **conservation** ethic.

Leopold suggested that increased ecological awareness would more finely tune people's perception of the world around them. The word aesthetics is, after all, derived from the Greek word *aisthesis*, literally "perception by the senses." Leopold claimed that perception, "like all real treasures of the mind, can be split into infinitely small fractions without losing its quality," a necessity if we are to revive our appreciation of the richness and diversity of the world that surrounds us. Instead, he thought that most recreationists are like "motorized ants who swarm the continents before learning to see [their] own back yard," so that recreational development becomes "a job not of building roads into lovely country, but of building receptivity into the still unlovely human mind."

Despite the fact that Thoreau and Leopold are both widely read by environmentalists and others, aesthetics has remained largely the domain of philosophy, and environmental aesthetics until recently a neglected domain in general. In philosophy, aesthetics has developed quite narrowly as an esoteric subdiscipline focused on theories of the arts, but a philosophy exclusive of **nature** and **environment**. An environmental philosophy has emerged in recent years, but this has developed mainly from the ethics tradition in philosophy and has, for some reason, neglected the aesthetic tradition (though Sepänmaa, and some other philosophers, have tried to encourage an environmental aesthetics at the intersection of traditions: on the environment as an aesthetic object and on environmental aesthetics as the philosophy of environmental criticism). While extensive literature has emerged on **environmental ethics**, the gap left by philosophy for environmental aesthetics has been filled by writers in a number of disciplines, notably psychology and geography, especially through empirical research on perception. Yi Fu Tuan's pioneering works (e.g., *Topophilia*, in 1974) broadened the study of aesthetics, transcended his own discipline of geography, and continue to shape the debate today about the content and concepts appropriate to an environmental aesthetic.

In classical aesthetics, sight and hearing are considered the primary senses since they are most immediately involved in the contemplation and appreciation of art and music. Arguably, the other three senses--touch, smell, and taste--must also be brought to bear for a true sensing of all the arts. Certainly, all five of the basic senses are central to an environmental aesthetic, an aesthetic sense, as Berleant notes, of all "the continuities that join integrated human persons with their natural and cultural condition." To achieve this, Berleant suggests, requires what he calls "an integrated sensorium," a "recognition of synaesthesia," i.e., a "fusion of the sense modalities." He claims that "perception is not passive but an active, reciprocal engagement with environment"; environmental aesthetics is what Berleant calls "an aesthetics of engagement."

Aesthetic engagement with environment involves not only the five senses, but the individual, behavioral and personal history of each person, as well as the cultural context and continuity in which that person has developed. An environmental aesthetic is "always contextual, mediated by the [long and complex] variety of conditions and influences that shape all [human] experience." An environmental aesthetic is also contingent on place. A **sense of place**, or a developed, knowledgeable understanding of the place in which one lives, is central to a well-developed environmental aesthetic. This can lead to greater engagement with place, and more involvement with local planning and land-use decisions, among other issues.

An understanding of environmental aesthetics cannot be attained without some notion of how the word and concept 'environment' itself is defined. Before recent publications on environmental aesthetics, most writers on the subject focused

on the beauty of nature, for example as experienced in the national parks of the United States. As a more formal environmental aesthetics has emerged, the definition of environment (and environmental beauty) has enlarged. Sepänmaa, for example, defines "environmental aesthetics [as] the aesthetics of the real world" and includes in this "all of the observer's external world: the natural environment, the cultural environment, and the constructed environment."

Berleant also claims that "the idea of an aesthetic environment is a new concept that enlarges the meaning of environment." But he considers environment not only as everything "out there," but as "everything that there is; it is all-inclusive, a total, integrated, continuous process." This conception is hard to grasp but "nonetheless soberly realistic, for it recognizes that ultimately everything affects everything else, that humans along with all other things inhabit a single intraconnected realm." Berleant's conception of environment "does not differentiate between the human and the natural and...interprets everything as part of a single, continuous whole." He advocates "the largest idea of environment [which] is the natural process as people live it, however they live it. Environment is nature experienced, nature lived." An environmental aesthetic then, depends on education in **human ecology**, on more complete understanding of how people connect with other people, and of how they interact with a wide range of environments, local to global.

Better understanding is both a result of, and a cause of, more engagement with place and surroundings. The resulting connections and commitment have ramifications for the design and planning of the built environment, and for exploiting and managing the natural environment. Aesthetics, in this ecological, integrated sense, can contribute to cost-benefit decisions about how we use the environments in which we live, including city and regional planning, and in design at all levels, from individual artifact to our grasp of the global realities of the contemporary world.

Berleant argues that environmental perception becomes an aesthetic only through a complete understanding of the totality. Though that is not possible for any one person, an appreciation of the richness and diversity of the earth's natural and human domain is necessary to achieve such an aesthetic. An environmental aesthetic then is necessarily complex, but it can also provide simple commandments for everyday life: as Thoreau suggested, "to affect the quality of the day, that is the highest of arts."

Environmental auditing

The environmental auditing movement gained momentum in the early 1980s as companies beset by new liabilities associated with Superfund and old **hazardous waste** sites wanted to insure that their operations were adhering to federal and local policies and company procedures. Most audits were initiated to avoid legal conflicts, and many companies brought in outside consultants to do the audits. The audits served many useful functions, including increasing management and employee awareness of environmental issues and initiating data collection and central monitoring of matters previously not watched as carefully. In many companies environmental auditing played a useful role in organizing information about the **environment**. It paved the way for the **pollution** prevention movement which had a great impact on company environmental management in the late 1980s when some companies started to view all of their pollution problems comprehensively and not in isolation from one another.

Environmental chemistry

Environmental chemistry refers to the occurrence, movements, and transformations of **chemicals** in the **environment**. Environmental chemistry deals with naturally occurring chemicals such as metals, other elements, organic chemicals, and biochemicals that are the products of biological **metabolism**. Environmental chemistry also deals with synthetic chemicals that have been manufactured by humans and dispersed into the environment, such as pesticides, **polychlorinated biphenyls** (PCBs), dioxins, **furans**, and many others.

The occurrence of chemicals refers to their presence and quantities in various compartments of the environment and ecosystems. For example, in a terrestrial **ecosystem** such as a forest, the most important compartments to consider are the mineral **soil**, water and air present in spaces within the soil, the above-ground **atmosphere**, dead **biomass** within the soil and lying on the ground as logs and other organic debris, and living organisms, the most abundant of which are trees. Each of these components of the forest ecosystem contains a wide variety of chemicals in some concentration, and in some amount. Chemicals move between all of these compartments, as fluxes that represent elements of **nutrient** and mineral cycles.

The movements of chemicals within and among compartments often involve a complex of transformations among

potential molecular states. There may also be changes in physical states, such as evaporation of liquids, or crystallization of dissolved substances. The transformations of chemicals among molecular states can be illustrated by reference to the environmental cycling of sulfur. Sulfur (S) is commonly emitted to the atmosphere as the gases **sulfur dioxide** (SO_2) or **hydrogen** sulfide (H_2S), which are transformed by photochemical reactions into the negatively-charged **ion**, sulfate (SO_4^{-2}). The sulfate may eventually be deposited with precipitation to a terrestrial ecosystem, where it may be absorbed along with soil water by tree roots, and later used to synthesize biochemicals such as proteins and amino acids. Eventually, the plant may die and its biomass deposited to the soil surface as litter. **Microorganisms** can then metabolize the organic matter as a source of energy and nutrients, eventually releasing simple inorganic compounds of sulfur such as sulfate or hydrogen sulfide into the environment. Alternatively, the plant biomass may be harvested by humans and used as a fuel, with the organic sulfur being oxidized during **combustion** and emitted to the atmosphere as sulfur dioxide. Organic and mineral forms of sulfur also occur in **fossil fuels** such as **petroleum** and **coal**, and the combustion of those materials also results in an **emission** of sulfur dioxide to the atmosphere.

Contamination and pollution

Contamination and **pollution** both refer to the presence of chemicals in the environment, but it is useful to distinguish between these two conditions. Contamination refers to the presence of one or more chemicals in concentrations higher than normally occurs in the ambient environment, but not high enough to cause biological or ecological damages. In contrast, pollution occurs when chemicals occur in the environment in concentrations high enough to cause damages to organisms. Pollution results in toxicity and ecological changes, but contamination does not cause those damages.

Chemicals that are commonly involved in pollution include the gases sulfur dioxide and **ozone**, diverse kinds of pesticides, elements such as **arsenic**, **copper**, **mercury**, **nickel**, and selenium, and some naturally occurring biochemicals. In addition, large concentrations of nutrients such as phosphate and nitrate can cause eutrophication, a type of pollution associated with excessive **ecological productivity**. Although any of these chemicals can cause pollution in certain situations, they most commonly occur in concentrations too small to cause toxicity or other ecological damages.

Modern analytical chemistry has become extremely sophisticated, and this allows trace contamination of potentially toxic chemicals to be measured at levels that are much smaller than what is required to cause demonstrable physiological or ecological damages.

Environmental chemistry of the Aamosphere

Nitrogen gas (N_2) comprises about 79% of the mass of Earth's atmosphere, while 20% is oxygen (O_2), 0.9% argon (Ar), 0.035% **carbon dioxide** (CO_2), and the remainder composed of a variety of trace gases. The atmosphere also contains variable concentrations of water vapor, which can range from 0.01% in frigid arctic air to 5% in humid tropical air.

The atmosphere also can contain high concentrations of gases, vapors, or particulates that are potentially harmful to people, other animals, or vegetation, or that cause damages to buildings, art, or other materials. The most important gaseous air pollutants (listed alphabetically) are ammonia (NH_3), **carbon monoxide** (CO), fluoride (F, usually occurring HF), nitric oxide and nitrogen dioxide (NO and NO_2, together known as oxides of nitrogen, or NO_x), ozone (O_3), **peroxyacetyl nitrate** (PAN), and sulfur dioxide (SO_2).

Vapors of elemental mercury and **hydrocarbons** can also be air pollutants. Particulates with tiny diameters (less than 1μm) can also be important, including dusts containing such toxic elements as arsenic, copper, **lead**, nickel, and vanadium, organic aerosols that are emitted as **smoke** during combustions (including **toxins** known as **polycyclic aromatic hydrocarbons**), and non-reactive minerals such as silicates.

Some so-called "trace toxics" also occur in the atmosphere in extremely small concentrations. The trace toxics include persistent organochlorine chemicals such as the pesticides DDT and dieldrin, polychlorinated biphenyls (PCBs), and the **dioxin**, TCDD. Other, less persistent pesticides may also be air pollutants close to places where they are used.

Environmental chemistry of water

Earth's surface waters vary enormously in their concentrations of dissolved and suspended chemicals. Other than the water, the chemistry of oceanic water is dominated by sodium chloride (NaCl), which has a typical concentration of about 3.5% or 35 g/l. Also important are sulfate (2.7 g/l), magnesium (1.3 g/l), and potassium and calcium (both 0.4 g/l). Some saline lakes can have much larger concentrations of dissolved ions, such as Great Salt Lake in Utah, which contains more than 20% salts.

Fresh waters are much more dilute in ions, although the concentrations are variable among waterbodies. The most important cations in typical fresh waters are calcium (Ca^{2+}), magnesium (Mg^{2+}), sodium (Na^+), ammonium (NH_4^+), and hydrogen ion (H^+; this is only present in acidic waters, otherwise hydroxy ion or OH^- occurs). The most important anions are bicarbonate (HCO_{3-}) sulfate (SO_4^{2+}), chloride (Cl^-), and nitrate (NO_3^-). Some fresh waters have high concentrations of dissolved organic compounds, known

as humic substances, which can stain the water a tea-like color. Typical concentrations of major ions in fresh water are: calcium 15 mg/l, sulfate 11 mg/l, chloride 7 mg/l, silica 7 mg/l, sodium 6 mg/l, magnesium 4 mg/l, and potassium 3 mg/l.

The water of clean precipitation is considerably more dilute than that of surface waters such as lakes. For example, precipitation at a remote place in Nova Scotia contained 1.6 mg/l of sulfate, 1.3 mg/l chloride, 0.8 mg/l sodium, 0.7 mg/l nitrate, 0.13 mg/l calcium, 0.08 mg/l ammonium, 0.08 mg/l magnesium, and 0.08 mg/l potassium. Because that site is about 31 mi (50 km) from the Atlantic Ocean, its precipitation is influenced by sodium and chloride originating with sea spray. In comparison, a more central location in North America had a sodium concentration of 0.09 mg/l and chloride 0.15 mg/l.

Pollution of surface waters is most often associated with the dumping of human or industrial sewage, nutrient inputs from agriculture, **acidification** caused by acidic precipitation or by acid-mine **drainage**, and industrial inputs of toxic chemicals. Eutrophication is caused when nutrient inputs cause large increases in aquatic productivity, especially in fresh waters and shallow marine waters into which sewage is dumped or that receive **runoff** containing agricultural fertilizers. In general, marine ecosystems become eutrophic when they are fertilized with nitrate, and freshwater systems with phosphate. Only 35–100 μg/l or more of phosphate is enough to significantly increase the productivity of most shallow lakes, compared with the background concentration of about 10 μg/l or less.

Freshwater ecosystems can become acidified by receiving drainage from bogs, by the deposition of acidifying substances from the atmosphere (such as acidic rain), and by acid-mine drainage. Atmospheric depositions have caused a widespread acidification of surface waters in eastern North America, Scandinavia, and other places. Surface waters acidified by atmospheric depositions commonly develop pHs of about 4.5–5.5. Tens of thousands of lake and running-water ecosystems have been damaged in this way. Acidification has many biological consequences, including toxicity caused to many **species** of plants and animals, including fish.

Some industries emit metals to the environment, and these may pollute fresh and marine waters. For instance, lakes near large smelters at **Sudbury, Ontario**, have been polluted by sulfuric **acid**, copper, nickel, and other metals, which in some cases occur in concentrations large enough to cause toxicity to aquatic plants and animals.

Mercury contamination of fish is also a significant problem in many aquatic environments. This phenomenon is significant in almost all large fish and **sharks**, which accumulate mercury progressively during their lives and commonly have residues in their flesh that exceed 0.5 ppm (this is the criterion set by the World Health Organization for the maximum concentration of mercury in fish intended for human consumption). It is likely, however, that the oceanic mercury is natural in origin, and not associated with human activities. Many fresh-water fish also develop high concentrations of mercury in their flesh, also commonly exceeding the 0.5 ppm criterion. This phenomenon has been demonstrated in many remote lakes. The source of mercury may be mostly natural, or it may originate with industrial sources whose emissions are transported over a long distance in the atmosphere before they are deposited to the surface. Severe mercury pollution has also occurred near certain factories, such as chlor-alkali plants and pulp mills. The most famous example occurred at Minamata, Japan, where industrial discharges led to the pollution of marine organisms, and then resulted in the **poisoning** of fish-eating animals and people.

Environmental chemistry of soil and rocks

The most abundant elements in typical soils and rocks are oxygen (47%), silicon (28%), **aluminum** (8%), and iron (3–4%). Virtually all of the other stable elements are also present in soil and rocks, and all of these can occur in a great variety of molecular forms and minerals. Under certain circumstances, some of these chemicals can occur in relatively high concentrations, sometimes causing ecological damages.

This can occur naturally, as in the case of soils influenced by so-called serpentine minerals, which can contain hundreds to thousands of ppm of nickel. In addition, industrial emissions of metals from smelters have caused severe pollution. Soils near Sudbury, for example, can contain nickel and copper concentrations up to 5,000 ppm each. Even urban environments can be severely contaminated by certain metals. Soils collected near urban factories for **recycling** old **automobile** batteries can contain lead in concentrations in the percent range, while the edges of roads can contain thousands of ppm of lead emitted through the use of leaded **gasoline**.

Trace toxics

Some chemicals occur in minute concentrations in water and other components of the environment, yet still manage to cause significant damages. These chemicals are sometimes referred to as trace toxics. The best examples are the numerous compounds known as halogenated hydrocarbons, particularly **chlorinated hydrocarbons** such as the insecticides DDT, DDD, and dieldrin, the dielectric fluids PCBs, and the chlorinated dioxin, TCDD. These chemicals are not easily degraded by either **ultraviolet radiation** or by metabolic reactions, so they are persistent in the environment. In addition, chlorinated hydrocarbons are virtually insoluble in water, but are highly soluble in lipids such as fats and oils. Because most lipids in ecosystems occur within the bodies of organisms, chlorinated hydrocarbons have a marked tendency to bioaccumulate (i.e., to occur preferen-

tially in organisms rather than in the non-living environment). This, coupled with the persistence of these chemicals, results in their strong tendency to food-chain/web accumulate or biomagnify (i.e., to occur in their largest concentrations in top predators).

Fish-eating birds are examples of top predators that have been poisoned by exposure to chlorinated hydrocarbons in the environment. Some examples of species that have been affected by this type of ecotoxicity include the **peregrine falcon** (*Falco peregrinus*), **bald eagle** (*Haliaeetus leucocephalus*), osprey (*Pandion haliaetus*), **brown pelican** (*Pelecanus occidentalis*), **double-crested cormorant** (*Phalacrocorax auritus*), and western grebe (*Aechmophorus occidentalis*). Concentrations of chlorinated hydrocarbons in the water of aquatic habitats of these birds is generally less than 1 μg/l (part per billion, or ppb), and less than 1 ng/l (part per trillion, or ppt) in the case of TCDD. However, some of the chlorinated hydrocarbons can biomagnify to tens to hundreds of mg/kg (ppm) in the fatty tissues of fish-eating birds. This can cause severe toxicity, characterized by reproductive failures, and even the deaths of adult birds, both of which can cause populations to collapse.

Other trace toxics also cause ecological damages. For example, although it is only moderately persistent in aquatic environments, the insecticide carbofuran can accumulate in acidic standing water in recently treated fields. If geese, ducks, or other birds or mammals utilize those temporary aquatic habitats, they can be killed by the carbofuran residues. Large numbers of **wildlife** have been killed this way in North America.

Petroleum

Water pollution can also result from the occurrence of hydrocarbons in large concentrations, especially after spills of crude oil or its refined products. Oil pollution can result from accidental spills of petroleum from wrecked tankers, offshore drilling platforms, broken pipelines, and from spills during warfare, as occurred during the Gulf War of 1991. Other important sources of oil pollution include operational discharges from tankers disposing oily bilge waters, and chronic releases from oil refineries and **urban runoff**.

The concentration of natural hydrocarbons in seawater is about 1 ppb, mostly due to releases from **phytoplankton** and bacteria. Beneath a slick of petroleum spilled at sea, however, the concentration of dissolved hydrocarbons can exceed several ppm, enough to cause toxicity to some organisms. There are also finely suspended droplets of petroleum in water beneath slicks, as a result of wave action on the floating oil. The slick and the sub-surface emulsion of oil-in-water are highly damaging to organisms that become coated with these substances.

Environmental Defense

Environmental Defense is a **public interest group** founded in 1967 and concerned primarily with the protection of the **environment** and the concomitant improvement of public health. Originally called Environmental Defense Fund, the name was shortened to end confusion related to the use of the word fund. In the beginning a group of Long Island scientists organized to oppose local spraying of the **pesticide** DDT, and Environmental Defense is still staffed by scientists as well as lawyers and economists. Over time the group has expanded its interests to include **air quality**, energy, **solid waste**, **water resources**, agriculture, **wildlife**, habitats, and international environmental issues. Environmental Defense presently has a membership of approximately 300,000, an annual budget of $39.1 million, and a staff of 200 working out of eight regional offices.

Environmental Defense seeks to protect the environment by initiating legal action in environment-related matters and also by conducting public service and educational campaigns. It publishes a newsletter detailing the organization's activities, as well as occasional books, reports, and monographs. Environmental Defense also conducts and encourages research relevant to environmental issues and promotes administrative, legislative, and corporate actions and policies in defense of the environment.

Environmental Defense's strategies and orientation have changed somewhat over the years from the early days when the group's motto was "Sue the bastards!" At about the time that Frederic D. Krupp became its executive director in 1984, Environmental Defense began to view environmental problems more in view of economic needs. As Krupp put it, the practical effectiveness of the environmental movement in the future would depend on its realization that behind environmental problems "there are nearly always legitimate social needs–and that long-term solutions lie in finding alternative ways to meet those underlying needs."

With this in mind, Krupp proposed a "third stage of environmentalism" which combined direct opposition to environmentally harmful practices with proposals for realistic, economically-viable alternatives. This strategy was first applied successfully to large-scale power production in California, where utilities were planning a massive expansion of

generating capacity. Environmental Defense demonstrated that this expansion was largely unnecessary (thereby saving the utilities and their customers a considerable amount of money while also protecting the environment) by showing that the use of existing and well-established technology could greatly reduce the need for new capacity without affecting the utility's customers. Environmental Defense also showed that it was economically effective to buy power generated from **renewable energy** resources, including **wind energy**.

The Environmental Defense worked with the McDonalds Corporation in 1991 on a task force to reduce the fast food giant's estimated two million lb-per-day (907,184 kg) effusion of waste. One of the most widely publicized results of these efforts was that McDonald's was convinced to stop packaging its hamburgers in **polystyrene** containers. Combined with other strategies, McDonald's estimates that the task force's recommendations will eventually reduce its waste flow by 75%. More recently in 2000, the Environmental Defense joined with eight companies to reduce the amount of **greenhouse gases** in the environment. In 2001, the Action Network (which has 750,000 members) and For My World projects were set up to inform the public on environmental and health issues. Scorecard.org rates area pollutants based on the most recent findings by the **Environmental Protection Agency** (EPA).

Environmental Defense continues to search for ways to harness economic forces in ways that destroy incentives to degrade the environment. This approach has made Environmental Defense one of the most respected and heeded environmental groups among United States corporations. Environmental Defense virtually ghost-wrote the Bush Sr. Administration's **Acid Rain** Bill, which makes considerable use of market-oriented strategies such as the issuing of tradable emissions permits. These permits allow for a set amount of **pollution** per firm based on ceilings set for entire industries. Companies can buy, sell, and trade these permits, thus providing them with a profit motive to reduce harmful emissions.

Environmental degradation

Degradation is the act or process of reducing something in value or worth. Environmental degradation, therefore, is the de-valuing of and damage to the **environment** by natural or **anthropogenic** causes. The loss of **biodiversity**, **habitat** destruction, depletion of energy or mineral sources, and exhaustion of **groundwater** aquifers are all examples of environmental degradation.

Presently there are four major areas of global concern due to environmental degradation: marine environment, **ozone** layer, **smog** and **air pollution**, and the vanishing **rain forest**. **Pollution**, at some level, is found throughout the world's oceans, which cover two-thirds of the planet's surface. Marine debris, farm **runoff**, industrial waste, sewage, dredge material, stormwater runoff, and **atmospheric deposition** all contribute to **marine pollution**. The level of degradation varies from region to region, but its effects are seen in such remote places as **Antarctica** and the Bering Sea.

Issues of **waste management** and disposal have had a large degrading impact on these areas. There are major national and international efforts to control pollution from shipping (including **oil spills** and general pollution due to ship ballast) and direct ocean or **estuary** discharges. Clean up has been started in some areas with some initial success.

Another major problem facing the world is the depletion of the ozone layer, which is linked to the use of a group of **chemicals** called **chlorofluorocarbons** (CFCs). These chemicals are widely used by industry as refrigerants and in **polystyrene** products. Once released into the air they rise to the **stratosphere** and eat away at the ozone layer. This layer is important because it protects us from harmful **ultraviolet radiation**, which is the chief cause of skin **cancer**.

Smog in urban areas and **air quality** in general have become crucial issues in the last few decades. **Acid rain**, which occurs when **sulfur dioxide** and **nitrogen** oxide—as emissions from **power plants** and industries—change in the **atmosphere** to form harmful compounds that fall to earth in rain, fog, and snow. **Acid** rain damages lakes and streams as well as buildings and monuments. Air **visibility** is curtailed and the health of humans as well as plants and trees can be affected.

Automobile emissions of **nitrogen oxides**, **carbon monoxide**, and volatile organic compounds—although much reduced in the United States—also contribute to smog and acid rain. **Carbon** monoxide continues to be a problem in cities such as Los Angeles where there is heavy **automobile** congestion.

The vanishing rain forest is also of major global concern. The degradation of the rain forest—with its extensive **logging**, **deforestation**, and massive destruction of habitat—has threatened the survival of many **species** of plants

and animals as well as disrupting **climate** and weather patterns locally and globally. Although tropical rain forests cover only about five to seven percent of the world's land surface, they contain about one-half to two-thirds of all species of plants and animals, some which have never been studied for their medicinal or food properties.

The problem of environmental degradation has been addressed by various environmental organizations throughout the world. Environmentalists are no longer solely concerned with the local region and efforts to stop or at least slow down environmental degradation has taken on a global significance.

Environmental design

Environmental design is a new approach in planning consumer products and industrial processes that are ecologically intelligent, sustainable, and healthy for both humans and our **environment**. Based on the work of innovative thinkers such as architect Bill McDonough, chemist Michael Braungart, physicist Amory Lovins, Swedish physician Dr. Karl-Henrik Robert, and business executive Paul Hawken, this movement is an effort to rethink our whole industrial economy. During the first Industrial Revolution 200 years ago, raw materials such as lumber, minerals, and clean water seemed inexhaustible, while **nature** was regarded as a hostile force to be tamed and civilized. We use materials to make the things we wanted, then discard them when they no longer are useful. "Dilution is the solution to pollution," suggests that if we just spread our wastes out in the environment widely enough, no one will notice.

This approach has given us an abundance of material things, but also has produced massive **pollution** and **environmental degradation**. It also is incredibly wasteful. On average, for every truckload of products delivered in the United States, 32 truckloads of waste are produced along the way. The **automobile** is a typical example. Industrial ecologist, Amory Lovins, calculates that for every 100 gallons (380 l) of **gasoline** burned in your car engine, only 1% (0 gal or 3.8 l) actually moves the passengers inside. All the rest is used to move the vehicles itself. The wastes produced—carbon dioxide, **nitrogen oxides**, unburned hydrocarbon, **rubber** dust, heat—are spread through the environment where they pollute air, water, and **soil**. And when the vehicle wears out after only a few years of service, thousands of pounds of metal, rubber, plastic, and glass become part of our rapidly growing waste steam.

This isn't the way things work in nature, environmental designers point out. In living systems, almost nothing is discarded or unused. The wastes from one organism become the food of another. Industrial processes, to be sustainable over the long term, should be designed on similar principles, designers argue. Rather than following current linear patterns in which we try to maximize the throughput of materials and minimize labor, products and processes should be designed to be energy efficient and use renewable materials. They should create products that are durable and reusable or easily dismantled for repair and remanufacture, and are non-polluting throughout their entire life cycle. We should base our economy on renewable **solar energy** rather than **fossil fuels**. Rather than measure our economic progress by how much material we use, we should evaluate productivity by how many people are gainfully and meaningfully employed. We should judge how well we're doing by how many factories have no smokestacks or dangerous effluents. We ought to produce nothing that will require constant vigilance from **future generations**.

Inspired by how ecological systems work, Bill McDonough proposes three simple principles for designing processes and products:

- Waste equals food. This principle encourages elimination of the concept of waste in industrial design. Every process should be designed so that the products themselves, as well as leftover **chemicals**, materials, and effluents, can become "food" for other processes.
- Rely on current solar income. This principle has two benefits: First, it diminishes, and may eventually eliminate, our reliance on hydrocarbon fuels. Second, it means designing systems that sip energy rather than gulping it down.
- Respect diversity. Evaluate every design for its impact on plant, animal, and human life. What effects do products and processes have on identity, independence, and integrity of humans and natural systems? Every project should respect the regional, cultural, and material uniqueness of its particular place.

According to McDonough, our first question about a product is whether it is really needed. Could we obtain the same satisfaction, comfort, or utility in another way that would have less environmental and social impacts? Can the things we design be restorative and regenerative: that is,

can they help reduce the damage done by earlier, wasteful approaches, and can they help nature heal rather than simply adding to existing problems? McDonough invites us to reinvent our businesses and institutions to work with nature, and redefine ourselves as consumers, producers, and citizens to promote a new sustainable relationship with the Earth. In an eco-efficient economy, he says, products might be divided into three categories:

- Consumables are products like food, natural fabrics, or paper that are produced from renewable materials and can go back to the soil as compost.
- Service products are durables such as cars, televisions, and refrigerators. These products should be leased to the customer to provide their intended service, but would always belong to the manufacturer. Eventually, they would be returned to the maker, who would be responsible for **recycling** or remanufacturing.
- Unmarketables are materials like radioactive isotopes, persistent **toxins**, and bioacumulative chemicals. Ideally, no one would make or use these products. But because eliminating their use will take time, McDonough suggests that for now, these materials should belong to the manufacturer and be molecularly tagged with the maker's mark. If they are discovered to be discarded illegally, the manufacturer would be liable.

Following these principles McDonough Braungart Design Chemistry has created nontoxic, easily recyclable, healthy materials for buildings and for consumer goods. Rather than design products for a "cradle to grave" life cycle, MBDC aims for a fundamental conceptual shift to a Cradle to Cradle® processes whose materials perpetually circulate in closed systems that create value and are inherently healthy and safe. Among some important examples are carpets designed to be recycled at the end of their useful life, paints and adhesives that are non-toxic and non-allergenic, and clothing that is both healthy for the wearer and that has minimal environmental impact in its production.

In his architecture firm, McDonough + partners, these new design models and environmentally friendly materials have been used in a number of innovative building projects. A few notable examples include: The Gap Inc. offices in California and the Environmental Studies building at Oberlin College in Ohio.

Built in 1994, The Gap building in San Bruno, California, is designed to maintain the unique natural features of the site while providing comfortable, healthy, and flexible office spaces. Intended to promote employee well-being and productivity as well as eco-efficiency, The Gap building has high ceilings, open, airy spaces, a natural ventilation system including operable windows, a full-service fitness center (including a pool), and a landscaped atrium for each office bay that brings the outside in. Skylights in the roof deliver daylight to interior offices and vent warm, stale air. Warm interior tones and natural woods (all wood used in the building was harvested by certified sustainable methods) give a friendly feel. Paints, adhesives, and floor coverings are low toxicity to maintain a healthy indoor environment. A pleasant place to work, the offices help recruit top employees and improve both effectiveness and retention.

The roof of The Gap Building is planted with native grasses and wildflowers that absorb rainwater and help improve ambient environmental quality. The grass roof also is beautiful and provides thermal and acoustic insulation. At night, cool outdoor air is flushed through the building to provide natural cooling. By providing abundant daylight, high-efficiency fluorescent lamps, fresh air ventilation, and other energy-saving measures, this pioneering building is more than 30% more energy efficient than required by California law. Operating savings within the first four to eight years of occupancy are expected to repay the initial costs of these design innovations.

An even more environmentally friendly building was built at Oberlin College in 2001 to house its Environmental Studies Program. Under the leadership of Dr. David Orr, the Adam Joseph Lewis Center is planned around the concept of ecological stewardship, and is intended to be both "restorative" and "regenerative" rather than merely non-damaging to the environment. The building is designed to be a net energy exporter, generating more power from renewable sources than it consumes annually. More than 3,700 sq ft (roughly 350 sq m) of photovoltaic panels on the roof are expected to generate 75,000 kilowatt hours of energy per year. The building also draws on geothermal **wells** for heating and cooling, and features use of natural daylight and ventilation to maintain interior comfort levels and a healthy interior environment. High efficiency insulation in walls and windows are expected to make energy consumption nearly 80% lower than standard academic buildings in the area.

The Lewis Center also incorporates an innovative "living machine" for internal waste **water treatment**, a constructed wetland for storm water management, and a landscape that provides social spaces, learning opportunities with live plants, and **habitat** restoration. It is expected that all water used in the building will be returned to the environment in as good quality as when it entered. The water produced by natural cleaning processes should be of high enough quality for drinking, although doing so isn't planned at present.

Taken together, these restorative and regenerative environmental design approaches could bring about a new industrial revolution. The features of environment design are incorporated in McDonough's "Hanover Principles" prepared for the 2000 World Fair in Hanover, Germany. This manifesto for green design urges us to recognize how humans

interact with and depends on the natural world. According to McDonough, we need to recognize even distant effects and consider all aspects of human settlement, including community, dwelling, industry and trade, in terms of existing and evolving connections between spiritual and material consciousness. We should accept responsibility for the consequences of design decisions upon human well being, the viability of natural systems. We have to understand the limitations of design. No human creation lasts forever, and design doesn't solve all problems. Those who create and plan should practice humility in the face of nature. We should treat nature as a model and mentor, not an inconvenience to be evaded and controlled. If we can incorporate these ecologically intelligent principles in our practice, we may be able to link long-term, sustainable considerations with ethical responsibility, and to reestablish the integral relationship between natural processes and human activity.

Environmental dispute resolution

Environmental Dispute Resolution (EDR) or Alternative Dispute Resolution (ADR), as it is more generally known, is an out-of-court alternative to litigation to resolve disputes between parties. Although ADR can be used with virtually any legal dispute, it is often used to resolve environmental disputes. There are several types of ADR, ranging from the least formal to the most formal process: (a) negotiation, (b) mediation, (c) adjudication, (d) arbitration, (e) minitrial, and (f) summary jury trial.

Negotiation: Negotiation is the simplest and most often practiced form of ADR. The parties do not enter the judicial system, but rather settlements are reached in an informal setting and then reduced to written terms.

Mediation: Mediation is an extension of the direct negotiation process. The term is loosely used and is often confused with arbitration or informal processes in general. Mediation is a process in which a neutral third-party intervenes to help disputants reach a voluntary settlement. The mediator has no authority to force the parties to reach an agreement.

Mediation is often the most appropriate technique for environmental disputes because the parties often have no prior negotiating relationship and, because there are often many technical and scientific uncertainties, the assistance of a qualified professional is helpful.

Mediation is also used with varying success in environmental policy-making, standard setting, determination of development choices, and the enforcement of environmental standards. Many states explicitly recognize mediation as the primary method for initially dealing with environmental disputes, and mediation procedures are written into federal **environmental policy**, specifically in the regulations dealing with the **Comprehensive Environmental Response, Compensation and Liability Act** (CERCLA) and the **Resource Conservation and Recovery Act** (RCRA). Mediation is not appropriate, however, with all environmental disputes because some environmental laws were designed to encourage a slower examination of issues that impact society.

Adjudication: Adjudication is sometimes referred to as "private judging." It is an ADR process in which the parties give their evidence and arguments to a neutral third-party who then renders an objective, binding decision. It is a voluntary procedure and private unless one party seeks judicial enforcement or review after the decision is made. The parties must agree on the adjudication and procedural rules for the process and each side is contractually bound for the length of the proceeding.

The advantage of adjudication is that a law- and/or environment-trained third party renders an objective decision based on the presented facts and legal arguments. The parties set their own rules so an adjudicator is not bound to legal principles of any particular jurisdiction. Private organizations provide adjudication services for fees but they can be expensive.

Arbitration: Arbitration is a process whereby a private judge, or arbitrator, hears the arguments of the parties and renders a judgment. The process works much like a court except that the parties choose the arbitrator and the substantive law he or she should apply. The arbitrator also has much more latitude in creating remedies which are fair to both parties. People often confuse the responsibilities of arbitrators and mediators. Arbitrators are passive functionaries who determine right or wrong; mediators are active functionaries who attempt to move the parties to reconciliation and agreement, regardless of who is right or wrong.

Parties cannot be forced into arbitration unless the contract in question includes an arbitration clause or the parties consented to enter into arbitration after the dispute developed. Since arbitration is a contractual remedy, the

arbitrator can consider only those disputes and remedies which the parties agreed to submit to arbitration.

Minitrial: A minitrial is a private process in which parties agree to voluntarily reach a negotiated settlement. They present their cases in summary form before a panel of designated representatives of each party. The panel offers non-binding conclusions on the probable outcome of the case, were it to be litigated. The parties may then use the results to assist with negotiation and settlement.

Summary Jury Trial: A summary jury trial is similar to a minitrial except that the evidence is presented to a non-expert, impartial jury, rather than a panel chosen by the parties, which subsequently prepares non-binding conclusions on each of the issues in dispute. Parties may then use the assessment of the jury's "verdict" to help with negotiation and settlement.

Environmental economics

Environmental economics is a relatively new field, but its roots go back to the end of the nineteenth century when economists first discussed the problem of **externality**. Economic transactions have external effects which are not captured by the price system. Prime examples of these externalities are **air pollution** and **water pollution**. The absence of a price for nature's capacity to absorb wastes has an obvious solution in economic theory. Economists advocate the use of surrogate prices in the form of **pollution** taxes and **discharge** fees. The non-priced aspect of the transaction then has a price, which sends a signal to the producers to economize on the use of the resource.

In addition to the theory of externalities, economists have recognized that certain goods, such as those provided by **nature**, are common property. Lacking a discrete owner, they are likely to be over-utilized. Ultimately, they will be depleted. Few will be left for **future generations**, unless common property goods like the air and water are protected.

Besides pollution taxes and discharge fees, economists have explored the use of marketable **emission** permits as a means of rectifying the market imperfection caused by pollution. Rather than establishing a unit charge for pollution, government would issue permits equivalent to an agreed-upon environmental standard. Holders of the permits would have the right to sell them to the highest bidder. The advantage of this system, wherein a market for pollution rights has been established, is that it achieves environmental quality standards. Under a charge system, trial-and-error tinkering would be necessary to achieve the standards.

Besides discharge fees and markets for pollution rights, economists have advocated the use of **cost-benefit analysis** in environmental decision making. Since control costs are much easier to measure than pollution benefits, economists have concentrated on how best to estimate the benefits of a clean **environment**. They have relied on two primary means of doing so. First, they have inferred from the actual decisions people make in the marketplace what value they place on a clean and healthy environment. Second, they have directly asked people to make trade-off choices. The inference method might rely on residential property values, decomposing the price of a house into individual attributes including **air quality**, or it might rely on the wage premium risky jobs enjoy. Despite many advances, the problem of valuing environmental benefits continues to be controversial with special difficulties surrounding the issues of quantifying the value of a human life, recreational benefits, and ecological benefits including **species** and **habitat** survival.

For instance, the question of how much a life is worth is repellent and absurd since human worth cannot be truly captured in monetary terms. Nonetheless it is important to determine the benefits for cost-benefit purposes. The costs of reducing pollution often are immediate and apparent, while the benefits are far-off and hard to determine. So, it is important to try to gauge what these benefits might be worth.

Economists call for a more rational ordering of risks. The funds for risk reduction are not limitless, and the costs keep mounting. Risks should be viewed in a detached and analytical way. Polls suggest that Americans worry most about such dangers as **oil spills**, **acid rain**, pesticides, **nuclear power**, and hazardous wastes, but scientific risk assessments show that these are only low or medium-level dangers. The greater hazards come from **radon**, **lead**, indoor air pollution, and fumes from **chemicals** such as **benzene** and formaldehyde. Radon, the odorless gas that naturally seeps up from the ground and is found in people's homes, causes as many as 20,000 lung **cancer** deaths per year, while **hazardous waste** dumps cause at most 500 cancer deaths. Yet the **Environmental Protection Agency** (EPA) spends over $6 billion a year to clean up hazardous waste sites while its spends only $100 million a year for radon protection. To test a home for radon costs about $25, and to clean it up if it is found contaminated costs $1,000. To make the entire national housing stock free from radon

would cost a few billion dollars. In contrast, projected spending for cleaning up hazardous waste sites is likely to exceed $500 billion despite the fact that only about 11 percent of such sites pose a measurable risk to human health.

Greater rationality would mean that less attention would be paid to some risks and more attention to others. For instance, scientific **risk assessment** suggests that sizable new investments will be needed to address the dangers of **ozone layer depletion** and greenhouse warming. **Ozone** depletion is likely to result in 100,000 more cases of skin cancer by the year 2050. Global warming has the potential to cause massive catastrophe.

For businesses, risk assessment provides a way to allocate costs efficiently. They are increasingly using it as a management tool. To avoid another accident like **Bhopal, India**, Union Carbide has set up a system by which it rates its plants "safe," "made safer," or "shut down." Environmentalists, on the other hand, generally see risk assessment as a tactic of powerful interests used to prevent regulation of known dangers or permit building of facilities where there will be known fatalities. Even if the chances of someone contracting cancer and dying is only one in a million, still someone will perish, which the studies by **risk assessors** indeed document. Among particularly vulnerable groups of the population (allergy sufferers exposed to benzene for example) the risks are likely to be much greater, perhaps as great as one fatality for every 100 persons. Environmentalists conclude that the way economists present their findings is too conservative. By treating everyone alike, they overlook the real danger to particularly vulnerable people. Risk assessment should not be used as an excuse for inaction.

Environmentalists have also criticized environmental economics for its emphasis on economic growth without considering the unintended side-effects. Economists need to supplement estimates of the economic costs and benefits of growth with estimates of the effects of that growth that cannot be measured in economic terms. Many environmentalists also believe that the **burden of proof** should rest with new technologies, in that they should not be allowed simply because they advance material progress. In affluent societies especially, economic expansion is not necessary.

Growth is promoted for many reasons to restore the balance of payments, to make the nation more competitive, to create jobs, to reduce the deficit, to provide for the old and sick, and to lessen poverty. The public is encouraged to focus on **statistics** on productivity, balance of payments, and growth, while ignoring the obvious costs. Environmental groups, on the other hand, have argued for a **steady-state economy** in which population and per capita resource consumption stabilize. It is an economy with a constant number of people and goods, maintained at the lowest feasible flows of matter and energy. Human services would play a large role in a steady-state economy because they do not require much energy or material throughput and yet contribute to economic growth. Environmental clean-up and **energy conservation** also would contribute, since they add to economic growth while also having a positive effect on the environment.

Growth can continue, according to environmentalists, but only if the forms of growth are carefully chosen. Free time, in addition, would have to be a larger component of an environmentally-acceptable future economy. Free time removes people from potentially harmful production. It also provides them with the time needed to implement alternative production processes and techniques, including **organic gardening**, **recycling**, public **transportation**, and home and appliance maintenance for the purposes of energy **conservation**.

Another requirement of an environmentally acceptable economy is that people accept a *new frugality*, a concept that also has been labeled *joyous austerity*, *voluntary simplicity*, and *conspicuous frugality*.

Economists represent the environment's interaction with the economy as a materials balance model. The production sector, which consists of mines and factories, extracts materials from nature and processes them into goods and services. Transportation and distribution networks move and store the finished products before they reach the point of consumption. The environment provides the material inputs needed to sustain economic activity and carries away the wastes generated by it. People have long recognized that nature is a source of material inputs to the economy, but they have been less aware that the environment plays an essential role as a receptacle for society's unwanted by-products. Some wastes are recovered by recycling, but most are absorbed by the environment. They are dumped in landfills, treated in incinerators, and disposed of as ash. They end up in the air, water, or **soil**.

The ultimate limits to economic growth do not come only from the availability of raw materials from nature. Nature's limited capacities to absorb wastes also set a limit on the economy's ability to produce. Energy plays a role in this process. It helps make food, forest products, chemicals, **petroleum** products, metals, and structural materials such as stone, steel, and cement. It supports materials processing by providing electricity, heating, and cooling services. It aids in transportation and distribution. According to the law of the conservation of energy, the material inputs and energy that enter the economy cannot be destroyed. Rather they change form, finding their way back to nature in a disorganized state as unwanted and perhaps dangerous by-products.

Environmentalists use the laws of physics (the notion of entropy) to show how society systematically dissipates low entropy, highly concentrated forms of energy by converting it

to high entropy, little concentrated waste that cannot be used again except at very high cost. They project current resource use and **environmental degradation** into the future to demonstrate that civilization is running out of critical resources. The earth cannot tolerate additional contaminants. Human intervention in the form of technological innovation and capital investment complemented by substantial human ingenuity and creativity is insufficient to prevent this outcome unless drastic steps are taken soon. Nearly every economic benefit has an environmental cost, and the sum total of the costs in an affluent society often exceed the benefits. The notion of **carrying capacity** is used to show that the earth has a limited ability to tolerate the disposal of contaminants and the depletion of resources.

Economists counter these claims by arguing that limits to growth can be overcome by human ingenuity, that benefits afforded by environmental protection have a cost, and that government programs to clean up the environment are as likely to fail as the market forces that produce pollution. The traditional economic view is that production is a function of labor and capital and, in theory, that resources are not necessary since labor and/or capital are infinitely substitutable for resources. Impending resource **scarcity** results in price increases which lead to technological substitution of capital, labor, or other resources for those that are in scarce supply. Price increases also create pressures for efficiency-in-use, leading to reduced consumption. Thus, resource scarcity is reflected in the price of a given commodity. As resources become scarce, their prices rise accordingly. Increases in price induce substitution and technological innovation.

People turn to less scarce resources that fulfill the same basic technological and economic needs provided by the resources no longer available in large quantities. To a large extent, the energy crises of the 1970s (the 1973 price shock induced by the Arab **oil embargo** and 1979 price shock following the Iranian Revolution) were alleviated by these very processes: higher prices leading to the discovery of additional supply and to conservation. By 1985, energy prices in real terms were lower than they were in 1973.

Humans respond to signals about scarcity and degradation. Extrapolating past consumption patterns into the future without considering the human response is likely to be a futile exercise, economists argue. As far back as the end of the eighteenth century, thinkers such as Thomas Malthus have made predictions about the limits to growth, but the lesson of modern history is one of technological innovation and substitution in response to price and other societal signals, not one of calamity brought about by resource exhaustion. In general, the prices of **natural resources** have been declining despite increased production and demand. Prices have fallen because of discoveries of new resources and because of innovations in the extraction and refinement process. *See also* Greenhouse effect; Trade in pollution permits; Tragedy of the Commons

Environmental education

Environmental education is fast emerging as one of the most important disciplines in the United States and in the world. Merging the ideas and philosophy of **environmentalism** with the structure of formal education systems, it strives to increase awareness of environmental problems as well as to foster the skills and strategies for solving those problems. Environmental issues have traditionally fallen to the state, federal, and international policymakers, scientists, academics, and legal scholars. Environmental education (often referred to simply as "EE") shifts the focus to the general population. In other words, it seeks to empower *individuals* with an understanding of environmental problems and the skills to solve them.

Background

The first seeds of environmental education were planted roughly a century ago and are found in the works of such writers as George Perkins Marsh, **John Muir**, **Henry David Thoreau**, and **Aldo Leopold**. Their writings served to bring the country's attention to the depletion of **natural resources** and the often detrimental impact of humans on the **environment**. In the early 1900s, three related fields of study arose that eventually merged to form the present-day environmental education.

Nature education expanded the teaching of biology, botany, and other natural sciences out into the natural world, where students learned through direct observation. **Conservation** education took root in the 1930s, as the importance of long-range, "wise use" management of resources intensified. Numerous state and federal agencies were created to tend public lands, and citizen organizations began forming in earnest to protect a favored animal, park, river, or other resource. Both governmental and citizen entities included

an educational component to spread their message to the general public. Many states required their schools to adopt conservation education as part of their curriculum. Teacher training programs were developed to meet the increasing demand. The Conservation Education Association formed to consolidate these efforts and help solidify citizen support for natural resource management goals. The third pillar of modern EE is outdoor education, which refers more to the method of teaching than to the subject taught. The idea is to hold classrooms outdoors; the topics are not restricted to environmental issues but includes art, music, and other subjects.

With the burgeoning of industrial output and natural resource depletion following World War II, people began to glimpse the potential environmental disasters looming ahead. The environmental movement exploded upon the public agenda in the late 1960s and early 1970s, and the public reacted emotionally and vigorously to isolated environmental crises and events. Yet it soon became clear that the solution would involve nothing short of fundamental changes in values, lifestyles, and individual behavior, and that would mean a comprehensive educational approach.

In August 1970, the newly-created **Council on Environmental Quality** called for a thorough discussion of the role of education with respect to the environment. Two months later, Congress passed the Environmental Education Act, which called for EE programs to be incorporated in all public school curricula. Although the act received little funding in the following years, it energized EE proponents and prompted many states to adopt EE plans for their schools. In 1971, the National Association for Environmental Education formed, as did myriad of state and regional groups.

Definition

What EE means depends on one's perspective. Some see it as a teaching method or philosophy to be applied to all subjects, woven into the teaching of political science, history, economics, and so forth. Others see it as a distinct discipline, something to be taught on its own. As defined by federal statute, it is the "education process dealing with people's relationships and their natural and manmade surroundings, and includes the relation of population, **pollution**, resource allocation and depletion, conservation, **transportation**, technology and urban and rural planning to the total human environment."

One of the early leaders of the movement is William Stapp, a former professor at the University of Michigan's School of Natural Resources and the Environment. His three-pronged definition has formed the basis for much subsequent thought: "Environmental education is aimed at producing a citizenry that is *knowledgeable* concerning the biophysical environment and its associated problems, *aware* of how to help solve these problems, and *motivated* to work toward their solution."

Many environmental educators believe that programs covering kindergarten through twelfth grade are necessary to successfully instill an environmental ethic in students and a comprehensive understanding of environmental issues so that they are prepared to deal with environmental problems in the real world. Further, an emphasis is placed on problem-solving, action, and informed behavioral changes. In its broadest sense, EE is not confined to public schools but includes efforts by governments, interest groups, universities, and news media to raise awareness. Each citizen should understand the environmental issues of his or her own community: land-use planning, traffic congestion, economic development plans, **pesticide** use, **water pollution** and **air pollution**, and so on.

International level

Concurrently with the emergence of EE in this country, other nations began pushing for a comprehensive approach to environmental problems within their own borders and on a global scale. In 1972, at the **United Nations Conference on the Human Environment** in Stockholm, the need for an international EE effort was clearly recognized and emphasized. Three years later, an International Environmental Education Workshop was held in Belgrade, from which emerged an eloquent, urgent mandate for the drastic reordering of national and international development policies. The "Belgrade Charter" called for an end to the military arms race and a new global ethic in which "no nation should grow or develop at the expense of another nation." It called for the eradication of poverty, hunger, illiteracy, pollution, exploitation, and domination. Central to this impassioned plea for a better world was the need for environmental education of the world's youth. That same year, the UN approved a $2 million budget to facilitate the research, coordination, and development of an international EE program among dozens of nations.

Effectiveness

There has been criticism over the last 15 years that EE too often fails to educate students and makes little difference in their behavior concerning the environment. Researchers and environmental educators have formulated a basic framework for how to improve EE: 1) Reinforce individuals for positive environmental behavior over an extended period of time. 2) Provide students with positive, informal experiences outdoors to enhance their "environmental sensitivity." 3) Focus instruction on the concepts of "ownership" and "empowerment." The first concept means that the learner has some personal interest or investment in the environmental issues being discussed. Perhaps the student can relate more readily to concepts of **solid waste** disposal if there is a **landfill** in the neighborhood. Empowerment gives

learners the sense that they can make changes and help resolve environmental problems. 4) Design an exercise in which students thoroughly investigate an environmental issue and then develop a plan for citizen action to address the issue, complete with an analysis of the social, cultural, and ecological consequences of the action.

Despite the efforts of environmental educators, the movement has a long way to go. The scope and number of critical environmental problems facing the world today far outweigh the successes of EE. Further, most countries still do not have a comprehensive EE program that prepares them, as future citizens, to make ecologically sound choices and to participate in cleaning up and caring for the environment. Lastly, educators, including the media, are largely focused on explaining the problems but fall short on explaining or offering possible solutions. The notion of "empowerment" is often absent.

Recent developments and successes in the United States

Project WILD, based in Boulder, Colorado, is a K–12 supplementary conservation and environmental education program emphasizing **wildlife** protection, sponsored by fish and wildlife agencies and environmental educators. The project sets up workshops in which teachers learn about wildlife issues. They in turn teach children and help students understand how they can act responsibly on behalf of wildlife and the environment. The program, begun in 1983, has grown tremendously in terms of the number of educators reached and the monetary support from states, which, combined, are spending about $3.6 million annually.

The Global Rivers Environmental Education Network (GREEN), begun at the University of Michigan under the guidance of William Stapp, has likewise been enormously successful, perhaps more so. Teachers all over the world take their students down to their local river and show them how to monitor **water quality**, analyze **watershed** usage, and identify socioeconomic sources of river degradation. Lastly, and most importantly, the students then present their findings and recommendations to the local officials. These students also exchange information with other GREEN students around the world via computers.

Another promising development is the National Consortium for Environmental Education and Training (NCEET), also based at the University of Michigan. The partnership of academic institutions, non-profit organizations, and corporations, NCEET was established in 1992 with a three-year, $4.8 million grant from the **Environmental Protection Agency** (EPA). Its main purpose is to dramatically improve the effectiveness of environmental education in the United States. The program has attacked its mission from several angles: to function as a national clearinghouse for K–12 teachers, to make available top-quality EE materials for teachers, to conduct research on effective approaches to EE, to survey and assess the EE needs of all 50 states, to establish a computer network for teachers needing access to information and resources, and to develop a teacher training manual for conducting EE workshops around the country.

Environmental enforcement

Environmental enforcement is the set of actions that a government takes to achieve full implementation of environmental requirements (compliance) within the regulated community and to correct or halt situations or activities that endanger the **environment** or public health. Experience with environmental programs has shown that enforcement is essential to compliance because many people and institutions will not comply with a law unless there are clear consequences for noncompliance. Enforcement by the government usually includes inspections to determine the compliance status of the regulated community and to detect violations; negotiations with individuals or facility managers who are out of compliance to develop mutually agreeable schedules and approaches for achievement of compliance; legal action when necessary to compel compliance and to impose some consequences for violation of the law or for posing a threat to public health and the environment; and compliance promotion, such as educational programs, technical assistance, and subsidies, to encourage voluntary compliance.

Nongovernmental groups may become involved in enforcement by detecting noncompliance, negotiating with violators, and commenting on governmental enforcement actions. They may also, if the law allows, take legal actions against a violator for noncompliance or against the government for not enforcing environmental requirements. The banking and insurance industries may be indirectly involved with enforcement by requiring assurance of compliance with

environmental requirements before they issue a loan or an insurance policy to a facility. Strong social sanctions for noncompliance with environmental requirements can also be effective to ensure compliance. For example, the public may choose to boycott a product if they believe the manufacturer is harming the environment.

Environmental enforcement is based on environmental laws. An **environmental law** provides the vision, scope, and authority for environmental protection and restoration. Some environmental laws contain requirements while others specify a structure and criteria for establishing requirements, which are then developed separately. Requirements may be general, in which they apply to a group of facilities, or facility-specific.

Examples of environmental enforcement programs include those that govern the ambient environment, performance, technology, work practices, dissemination of information and product or use bans.

Ambient standards (media quality standard) are goals for the quality of the ambient environment (that is, air and **water quality**). Ambient standards are usually written in units of concentration, and they are used to plan the levels of emissions that can be accommodated from individual sources while still meeting an area-wide goal. Ambient standards can also be used as triggers, i.e., when a standard is exceeded, monitoring or enforcement efforts are increased. Enforcement of these standards involves relating an ambient measurement to emissions or activities at a specific facility, which can be difficult.

Performance standards, widely used for regulations, permits, and monitoring requirements, limit the amount or rate of particular **chemicals** or discharges that a facility can release into the environment in a given period of time. These standards allow sources to choose which technologies they will use to meet the standards. Performance standards are often based on output that can be achieved by using the **best available control technology**. Some standards allow a source with multiple emissions to vary its emissions from each stack as long as the total sum of emissions does not exceed the permitted total. Compliance with **emission standards** is accomplished by sampling and monitoring, which in some cases may be difficult and/or expensive.

Technology standards require the regulated community to use a particular type of technology (i.e., "best available technology") to control and/or monitor emissions. Technology standards are effective if the equipment specified is known to perform well under the range of conditions experienced by the source. Compliance is measured by whether the equipment is installed and operating properly. However, proper operation over a long period of time is more difficult to monitor. The use of technology standards can inhibit technological innovation.

Practice standards require or prohibit work activities that may have environmental impacts (e.g., prohibition of carrying hazardous liquids in uncovered containers). Regulators can easily inspect for compliance and take action against noncomplying sources, but ongoing compliance is not easy to ensure.

Dissemination of information and product or use bans are also governed by environmental enforcement programs. Information standards require a source of potential **pollution** (e.g., a manufacturer or facility involved in generating, transporting, storing, treating, and disposing of hazardous wastes) to develop and submit information to the government. For example, a source generating pollution may be required to monitor, maintain records, and report on the level of pollution generated and whether or not the source exceeds performance standards. Information requirements are also used when a potential pollution source is a product such as a new chemical or **pesticide**. The manufacturer may be required to test and report on the potential of the product to cause harm if released into the environment. Finally, product or use bans are used to prohibit a product (i.e., ban the manufacture, sale, and/or use of a product) or they may prohibit particular uses of a product.

An effective environmental law should include the authority or power necessary for its own enforcement. An effective authority should govern implementation of environmental requirements, inspection, and monitoring of facilities, and legal sanctions for noncompliance. One type of authority that is used is guidance for the implementation of environmental laws by issuance of regulations, permits, licenses, and/or guidance policies. Regulations establish, in greater detail than is specified by law, general requirements that must be met by the regulated community. Some regulations are directly enforced while others provide criteria and procedures for developing facility-specific requirements utilizing permits and licenses to provide the basis of enforcement. Permits are used to control activities related to construction or operation of facilities that generate pollutants. Requirements in permits are based on specific criteria established in laws, regulations, and/or guidance. General permits specify what a class of facilities is required to do, while a facility-specific permit specifies requirements for a particular facility, often taking into account the conditions there. Licenses are permits to manufacture, test, sell, and/or distribute a product that may pose an environmental or public health risk if improperly used. Licenses may be general or facility-specific. Written guidance and policies, which are prepared by the regulator, are used to interpret and implement requirements to ensure consistency and fairness. Guidance may be necessary because not all applications of requirements can be anticipated, or when regulation is achieved by the use of facility-specific permits or licenses.

Authority is also required to provide for inspection and monitoring of facilities, with legal sanctions for noncompliance. Requirements may either be waived or prepared for facility-specific conditions. The authority will inspect regulated facilities and gain access to their records and equipment to determine if they are in compliance.

Authority is necessary to ensure that the regulated community monitors its own compliance, maintains records of its compliance activities and status, reports this information periodically to the enforcement program, and provides information during inspections.

An effective law should also include the authority to take legal action against noncomplying facilities, imposing a range of monetary penalties and other sanctions on facilities that violate the law, as well as criminal sanctions on those facilities or individuals who deliberately violate the law (e.g., facilities that knowingly falsify data). Also, power should be granted to correct situations that pose an immediate and substantial threat to public health and/or the environment.

The range and types of environmental enforcement response mechanisms available depend on the number and types of authorities provided to the enforcement program by environmental and related laws. Enforcement mechanisms may be designed to return violators to compliance, impose a sanction, or remove the economic benefits of noncompliance. Enforcement may require that specific actions be taken to test, monitor, or provide information. Enforcement may also correct environmental damages and modify internal company management problems.

Enforcement response mechanisms include informal responses such as phone calls, site visits and inspections, warning letters, and notices of violations, which are more formal than warning letters. They provide the facility manager with a description of the violation, what should be done to correct it, and by what date. Informal responses do not penalize but can lead to more severe responses if ignored. The more formal enforcement mechanisms are backed by law and are accompanied by procedural requirements to protect the rights of the individual. Authority to use formal enforcement mechanisms for a specific situation must be provided in the applicable environmental law. Civil administrative orders are legal, independently enforceable orders issued directly by enforcement program officials that define the violation, provide evidence of the violation, and require the recipient to correct the violation within a specified time period. If the recipient violates the order, program managers can take further legal action using additional orders or the court system to force compliance with the order.

Further legal action includes the use of field citations, which are administrative orders issued by inspectors in the field. They require the violator to correct a clear-cut violation and pay a small monetary fine. Field citations are used to handle more routine types of violations that do not pose a major threat to the environment. Legal action may also lead to civil judicial enforcement actions, which are formal lawsuits before the courts. These actions are used to require action to reduce immediate threats to public health or the environment, to enforce administrative orders that have been violated, and to make final decisions regarding orders that have been appealed. Finally, a criminal judicial response is used when a person or facility has knowingly and willfully violated the law or has committed a violation for which society has chosen to impose the most serious legal sanctions available. This response involves criminal sanction, which may include monetary penalties and imprisonment. The criminal response is the most difficult type of enforcement, requiring intensive investigation and case development, but it can also create a significant deterrence.

Environmental enforcement must include processes to balance the rights of individuals with the government's need to act quickly. A notice of violation should be issued before any action is taken so that the finding of violation can be contested, or so that the violation can be corrected before further government action. Appeals should be allowed at several stages in the enforcement process so that the finding of violation, the required remedial action, or the severity of the proposed sanction can be reviewed. There should also be dispute resolution processes for negotiations between program officials and the violator, which may include face-to-face discussions, presentations before a judge or hearing examiner, or use of third party mediators, arbitrators, or facilitators.

Environmental engineering

The development of environmental engineering as a discipline is a reflection of the modern need to maintain public health by providing safe drinking water and **sanitation**, and by treating and disposing of sewage, **municipal solid waste**, and **pollution**. Originally, sanitary engineering, a limited subdiscipline of civil engineering, performed some of these functions. But with the growth of concern for protecting the **environment** and the passage of laws regulating disposal of wastes, environmental engineering has grown into a discrete discipline encompassing a wide range of activities including: "proper disposal or **recycling** of **wastewater** and solid wastes, adequate **drainage** of urban and rural areas

for proper sanitation, control of water, **soil** and atmospheric pollution and the social and environmental impact of these solutions." Education for environmental engineers requires that they be "well informed concerning engineering problems in the field of public health, such as control of insect-borne diseases, the elimination of industrial health hazards, and the provision of adequate sanitation in urban, rural and recreational areas, and the effect of technological advance on the environment." More broadly environmental engineering is defined by W. E. Gilbertson as "that branch of engineering which is concerned with the application of scientific principles to (1) the protection of human populations from the effects of adverse environmental factors, (2) the protection of environments, both local and global, from the potentially deleterious effects of human activities, and (3) the improvement of environmental quality of man's health and well-being."

The American Academy of Environmental Engineers (AAEE) has defined environmental engineering as "the application of engineering principles to the management of the environment for the protection of human health; for the protection of nature's beneficial ecosystems and for environment-related enhancement of the quality of human life."

Degree-granting institutions in the United States do not necessarily consider environmental engineering as a separate discipline. A report by the U. S. Engineering Manpower Commission found that only 192 baccalaureate environmental engineering degrees were granted in 1988; however C. Robert Baillod estimates that at least 10% of the 8,800 annual graduates from baccalaureate civil engineering programs are educated to function as environmental engineers. If similar estimates are made for chemical, mechanical, geological and other engineers who function as environmental engineers, 1,000–2,000 graduates are entering the profession each year. Data collected by Baillod indicate that the supply of environmental engineers will satisfy half the demand for 2,000–5,000 new environmental engineering graduates per year for the next decade.

From 1970 to 1985, an increasing number of environmental statutes passed at the federal and state level in the United States while parallel legislation was being established internationally to regulate and control environmental pollution. In the United States, the establishment of the **Comprehensive Environmental Response, Compensation and Liability Act** (CERCLA)—known as *Superfund* for short—has provided the impetus for significant activity in **remediation** as well as providing industries and municipalities with incentives (such as liability for environmental damage) to clean up and avoid pollution. In order to comply with environmental laws and also to maintain good business practice, corporations are including impacts on the environment in planning for their process engineering. A serious potential for fines or costly liability suits exists if the design of processes is not carefully conducted with environmental safeguards.

In addition to employment by the private sector, state and federal governments also employ environmental engineers. The primary function of environmental engineers in government is research and development for implementation of regulations and their enforcement. At the federal level, agencies such as the **Environmental Protection Agency** (EPA), as well as the Departments of Commerce, Energy, Interior and Agriculture, employ environmental engineers.

Environmental engineering is proving crucial in addressing an array of environmental needs. Techniques recently conceived by environmental engineers include:

- The development of an oil-absorbing, floating sponge-like material as a re-usable first response material for remediating **oil spills** on open bodies of water.
- Design and operation of a plant to process electrolytic plating wastes collected from a large urban area to **reuse** the metals and detoxify the cyanide as a means of avoiding the discharges of these wastes into the sewer system.
- Development of a process for reusing the **lead**, zinc, and **cadmium** which would otherwise be lost as a fume in the remelting of automotive scrap to form steel products.
- Use of naturally-occurring bacterial agents in cleanup of underground aquifers contaminated by prior discharges of creosote, a substance used to preserve wood products.
- Development of processes for removal of and destruction of PCBs and other hazardous organic agents from spills into soil.
- Development of sensing techniques which enable tracing of pollution to point sources and the determination of the degree of pollution which has occurred for application of legal remedies.
- Development of process design and control instrumentation in nuclear reactors to prevent, contain and avoid nuclear releases.
- Design and development of **feedlots** for animals in which the waste products are made into reusable agricultural products.
- Development of sterilization, **incineration** and gas cleanup systems for treatment of hospital wastes.
- Certification of properties to verify the absence of factors which would make new owners liable to environmental litigation (for example, absence of **asbestos**, absence of underground storage tanks for hazardous material)s.
- Redesign of existing chemical plants to recycle or eliminate waste streams.
- Development of processes for recycling wastes (for example, processes for de-inking and reuse of newsprint or reuse of plastics).

These wide-ranging examples are typical of the solutions which are being developed by a new generation of technically-trained individuals. In an increasingly populated and industrialized world, environmental engineers will continue to play a pivotal role in devising technologies needed to minimize the impact of humans on the earth's resources.

Environmental estrogens

The United States **Environmental Protection Agency** (**EPA**) defines an environmental endocrine disruptor—the term the Agency uses for environmental estrogens—as "an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of **homeostasis**, reproduction, development, and/or behavior." Dr. Theo Colborn, a zoologist and senior scientist with the **World Wildlife Fund**, and the person most credited with raising national awareness of the issue, describes these **chemicals** as "hand-me-down poisons" that are passed from mothers to offspring and may be linked to a wide range of adverse effects, including low sperm counts, infertility, genital deformities, breast and prostate **cancer**, neurological disorders in children such as hyperactivity and attention deficits, and developmental and reproductive disorders in **wildlife**. Colborn discusses these effects in her 1996 book, *Our Stolen Future*—co-authored with Dianne Dumanoski and John Peterson Myers—which asks: "Are we threatening our fertility, intelligence, and survival?" Some other names used for the same class of chemicals are hormone disruptors, estrogen mimics, endocrine disrupting chemicals, and endocrine modulators.

While EPA takes the position that it is "aware of and concerned" about data indicating that exposure to environmental **endocrine disruptors** may cause adverse impacts on human health and the **environment**, the Agency at present does not consider endocrine disruption to be "an adverse endpoint *per se*." Rather, it is "a mode or mechanism of action potentially leading to other outcomes"—such as the health effects Colborn described drawing from extensive research of numerous scientists—but, in EPA's view, the link to human health effects remains an unproven hypothesis. For Colborn and a significant number of other scientists, however, enough is known to support prompt and far-reaching action to reduce exposures from these chemicals and myriad products that are manufactured using them. Foods, plastic packaging, and pesticides are among the sources of exposure Colborn raises concerns about in her book.

Ultimately, the environmental estrogens issue is about whether these chemicals are present in the environment at high enough levels to disrupt the normal functioning of wildlife and human endocrine systems and thereby cause harmful effects. The endocrine system is one of at least three important regulatory systems in humans and other animals (the nervous and immune systems are the other two) and includes such endocrine glands as the pituitary, thyroid, pancreas, adrenal, and the male and female gonads, or testes and ovaries. These glands secrete hormones into the bloodstream where they travel in very small concentrations and bind to specific sites called "cell receptors" in target tissues and organs. The hormones affect development, reproduction, and other bodily functions. The term "endocrine disruptors" includes not only estrogens but also antiandrogens and other agents that act on the endocrine system.

The question of whether environmental endocrine disruptors may be causing effects in humans has arisen over the past decade based on a growing body of evidence about effects in wildlife exposed to dichlorodiphenyl-trichlorethane (DDT), **polychlorinated biphenyls** (PCBs), and other chemicals. For instance, field studies have proven that tributyltin (TBT), which is used as an antifouling paint on ships, can cause "imposex" in female snails, which are now commonly found with male genitalia, including a penis and vas deferens, the sperm-transporting tube. TBT has also been shown to cause decreased egg production by the periwinkle (*Littorina littorea*). As early as 1985, concerns arose among scientists and the public in the United Kingdom over the effects of synthetic estrogens from birth control pills entering rivers, a concern that was heightened when anglers reported catching fish with both male and female characteristics. Other studies have found **Great Lakes salmon** to invariably have thyroids that were abnormal in appearance,

even when there were no overt goiters. Herring gulls (*Larus argentatus*) throughout the Great Lakes have also been found with enlarged thyroids. In the case of the salmon and gulls, no agent has been determined to be causing these effects. But other studies have linked DDT exposure in the Great Lakes to eggshell thinning and breakage among bald eagles and other birds. In Lake Apopka, Florida, male alligators (*Alligator mississippiensis*) exposed to a mixture of dicofol, DDT, and dichlorodiphenyldichloroethylene (DDE) have been "demasculinized," with phalluses one-half to one-fourth the normal size. Red-eared turtles (*Trachemys scripta*) in the lake have also been demasculinized. One 1988 study reported that four of 15 female black bears (*Ursus americanus*) and one of four female brown bears (*Ursus arctos*) had, to varying degrees, male sex organs. These and nearly 300 other peer-reviewed studies have led EPA—in conjunction with the multi-agency White House Committee on Environment and Natural Resources—to develop a "framework for planning" and an extensive research agenda to answer questions about the effects of endocrine disruptors. The goal is to better understand the potential effects of such chemicals on human beings before implementing regulatory actions.

The federal research agenda has been evolving through a series of workshops. As early as 1979, the **National Institute of Environmental Health Sciences** (NIEHS), based in Research Triangle Park, North Carolina, held an "Estrogens in the Environment" conference to evaluate the chemical properties and diverse structures among environmental estrogens. NIEHS held a second conference in 1985 that addressed numerous potential toxicological and biological effects from exposure to these chemicals. NIEHS's third conference, held in 1994, focused on detrimental effects in wildlife. At an April 1995 EPA-sponsored workshop on "Research Needs for the **Risk Assessment** of Health and Environmental Effects of Endocrine Disruptors," a number of critical research questions were discussed: What do we know about the carcinogenic effects of endocrine-disrupting agents in humans and wildlife? What are the research needs in this area, including the highest priority research needs? Similar questions were discussed for reproductive effects, neurological effects, immunological effects, and a variety of risk assessment issues. Drawing on the preceding conferences and workshops, in February 1997 EPA issued a *Special Report on Environmental Endocrine Disruption: An Effects Assessment and Analysis* that recommended key research needs to better understand how environmental endocrine disruptors may be causing the variety of specific effects in human beings and wildlife hypothesized by some scientists. For instance, male reproductive research should include tests that evaluate both the quantity and quality of sperm produced. Furthermore, when testing the endocrine-disrupting potential of chemicals, it is important to test for both estrogenic and antiandrogenic activity because new data suggest that it is possible the latter—antiandrogenic activity—not estrogenic activity, is causing male reproductive effects. In the area of ecological research, EPA's special report highlighted the need for research on such issues as what chemicals or class of chemicals can be considered genuine endocrine disruptors and what dose is needed to cause an effect.

Even before environmental estrogens received a place on the federal environmental agenda as a priority concern, Colborn and other scientists first met in July 1991 in Racine, Wisconsin, to discuss their misgivings about the prevalence of estrogenic chemicals in the environment. From that meeting came the landmark "Wingspread Consensus Statement" of 21 leading researchers. The statement asserted that the scientists were certain that a large number of human-made chemicals that have been released into the environment, as well as a few natural ones, "have the potential to disrupt the endocrine system of animals, including humans," and that many wildlife populations are already affected by these chemicals. Furthermore, the scientists expressed certainty that the effects may be entirely different in the embryo, fetus, or perinatal organisms than in the adult; that effects are more often manifested in offspring than in exposed parents; that the timing of exposure in the developing organism is crucial; and that, while embryonic development is the critical exposure period, "obvious manifestations may not occur until maturity." Besides these and other "certain" conclusions, the scientists estimated with confidence that "some of the developmental impairments reported in humans today are seen in adult offspring of parents exposed to synthetic hormone disruptors (agonists and antagonists) released in the environment" and that "unless the environmental load of synthetic hormone disruptors is abated and controlled, large scale dysfunction at the population level is possible." The Wingspread Statement included numerous other consensus views on what models predict and the judgment of the group on the need for much greater research and a comprehensive inventory of these chemicals.

The Food Quality Protection Act of 1996 (FQPA) and the **Safe Drinking Water Act** Amendments of 1996 require EPA to develop a screening program to determine whether pesticides or other substances cause effects in humans similar to effects produced by naturally occurring estrogens and other endocrine effects. The FQPA requires **pesticide** registrants to test their products for such effects and submit reports, and it requires that registrations be suspended if registrants fail to comply. Besides the EPA screening program, the **United Nations Environment Programme** is pursuing a multinational effort to manage "persistent organic pollutants," including DDT and PCBs, which, though banned in the United States, are still used elsewhere and can persist in the environment and be trans-

ported long-distance. In February 1997, Illinois became the first state to issue a strategy for endocrine disruptors that requires every Illinois EPA program to assess its current activities affecting these chemicals and to begin monitoring a list of known, probable, and suspected chemicals in case further action is needed in the future.

Environmental ethics

Ethics is a branch of philosophy that deals with morals and values. Environmental ethics refers to the moral relationships between humans and the natural world. It addresses such questions as, do humans have obligations or responsibilities toward the natural world, and if so, how are those responsibilities balanced against human needs and interests? Are some interests more important than others?

Efforts to answer such ethical questions have led to the development of a number of schools of ethical thought. One of these is **utilitarianism**, a philosophy associated with the English eccentric Jeremy Bentham and later modified by his godson John Stuart Mill. In its most basic terms, utilitarianism holds that an action is morally right if it produces the greatest good for the greatest number of people. The early environmentalist **Gifford Pinchot** was inspired by utilitarian principles and applied them to **conservation**. Pinchot proposed that the purpose of conservation is to protect **natural resources** to produce "the greatest good for the greatest number for the longest time." Although utilitarianism is a simple, practical approach to human moral dilemmas, it can also be used to justify reprehensible actions. For example, in the nineteenth century many white Americans believed that the extermination of native peoples and the appropriation of their land was the right thing to do. However, most would now conclude that the good derived by white Americans from these actions does not justify the genocide and displacement of native peoples.

The tenets of utilitarian philosophy are presented in terms of human values and benefits, a clearly anthropocentric world view. Many philosophers argue that only humans are capable of acting morally and of accepting responsibility for their actions. Not all humans, however, have this capacity to be moral agents. Children, the mentally ill, and others are not regarded as moral agents, but, rather, as moral subjects. However, they still have rights of their own—rights that moral agents have an obligation to respect. In this context, moral agents have **intrinsic value** independent of the beliefs or interests of others.

Although humans have long recognized the value of non-living objects, such as machines, minerals, or rivers, the value of these objects is seen in terms of money, aesthetics, cultural significance, etc. The important distinction is that these objects are useful or inspiring to some person—they are not ends in themselves but are means to some other end. Philosophers term this instrumental value, since these objects are the instruments for the satisfaction of some other moral agent. This philosophy has also been applied to living things, such as domestic animals. These animals have often been treated as simply the means to some humanly-desired end without any inherent rights or value of their own.

Aldo Leopold, in his famous essay on environmental ethics, pointed out that not all humans have been considered to have inherent worth and intrinsic rights. As examples he points to children, women, foreigners, and indigenous peoples—all of whom were once regarded as less than full persons; as objects or the property of an owner who could do with them whatever he wished. Most civilized societies now recognize that all humans have intrinsic rights, and, in fact, these intrinsic rights have also been extended to include such entities as corporations, municipalities, and nations.

Many environmental philosophers argue that we must also extend recognition of inherent worth to all other components of the natural world, both living and non-living. In their opinion, our anthropocentric view, which considers components of the natural world to be valuable only as the means to some human end, is the primary cause of **environmental degradation**. As an alternative, they propose a biocentric view which gives inherent value to all the natural world regardless of its potential for human use.

Paul Taylor outlines four basic tenets of biocentrism in his book, *Respect for Nature*. These are: 1) Humans are members of earth's living community in the same way and on the same terms as all other living things; 2) Humans and other **species** are interdependent; 3) Each organism is a unique individual pursuing its own good in its own way; 4) Humans are not inherently superior to other living things. These tenets underlie the philosophy developed by Norwegian Arne Naess known as **deep ecology**.

From this biocentric philosophy Paul Taylor developed three principles of ethical conduct: 1) Do not harm any natural entity that has a good of its own; 2) Do not try

to manipulate, control, modify, manage or interfere with the normal functioning of natural ecosystems, biotic communities, or individual wild organisms; 3) Do not deceive or mislead any animal capable of being deceived or misled. These principles led Professor Taylor to call for an end to **hunting**, fishing and **trapping**, to espouse **vegetarianism**, and to seek the exclusion of human activities from **wilderness** areas. However, Professor Taylor did not extend intrinsic rights to non-living natural objects, and he assigned only limited rights to plants and domestic animals. Others argue that all natural objects, living or not, have rights.

Regardless of the appeal that certain environmental philosophies may have in the abstract, it is clear that humans must make use of the natural world if they are to survive. They must eat other organisms and compete with them for all the essentials of life. Humans seek to control or eliminate harmful plants or animals. How is this intervention in the natural world justified? Stewardship is a principle that philosophers use the justify such interference. Stewardship holds that humans have a unique responsibility to care for domestic plants and animals and all other components of the natural world. In this view, humans, their knowledge, and the products of their intellect are an essential part of the natural world, neither external to it nor superfluous. Stewardship calls for humans to respect and cooperate with **nature** to achieve the greatest good. Because of their superior intellect, humans can improve the world and make it a better place, but only if they see themselves as an integral part of it.

Ethical dilemmas arise when two different courses of action each have valid ethical underpinnings. A classic ethical dilemma occurs when any course of action taken will cause harm, either to oneself or to others. Another sort of dilemma arises when two parties have equally valid, but incompatible, ethical interests. To resolve such competing ethical claims Paul Taylor suggests five guidelines: 1) it is usually permissible for moral agents to defend themselves; 2) basic interests, those interests necessary for survival, take precedence over other interests; 3) when basic interests are in conflict, the least amount of harm should be done to all parties involved; 4) whenever possible, the disadvantages resulting from competing claims should be borne equally by all parties; 5) the greater the harm done to a moral agent, the great is the compensation required.

Ecofeminists do not find that utilitarianism, biocentrism or stewardship provide adequate direction to solve environmental problems or to guide moral actions. In their view, these philosophies come out of a patriarchal system based on domination—of women, children, minorities and nature. As an alternative, ecofeminists suggest a pluralistic, relationship-oriented approach to human interactions with the **environment**. **Ecofeminism** is concerned with nurturing, reciprocity, and connectedness, rather than with rights, responsibilities, and ownership. It challenges humans to see themselves as related to others and to nature. Out of these connections, then, will flow ethical interactions among individuals and with the natural world. *See also* Animal rights; Bioregionalism; Callicott, J. Environmental health

Environmental health is concerned with the medical effects of **chemicals**, pathogenic (disease-causing) organisms, or physical factors in our **environment**. Because our environment affects nearly every aspect of our lives in some way or other, environmental health is related to virtually every branch of medical science. The special focus of this discipline, however, tends to be health effects of polluted air and water, contaminated food, and toxic or hazardous materials in our environment. Concerns about these issues makes environmental health one of the most compelling reasons to be interested in **environmental science**.

For a majority of humans, the most immediate environmental health threat has always been pathogenic organisms. Improved **sanitation**, nutrition, and modern medicine in the industrialized countries have reduced or eliminated many of the **communicable diseases** that once threatened us. But for people in the **less developed countries** where nearly 80% of the world's population lives, bacteria, viruses, **fungi**, **parasites**, worms, flukes, and other infectious agents remain major causes of illness and death. Hundreds of millions of people suffer from major diseases such as **malaria**, gastrointestinal infections (diarrhea, dysentery, **cholera**), tuberculosis, influenza, and pneumonia spread through the air, water, or food. Many of these terrible diseases could be eliminated or greatly reduced by a cleaner environment, inexpensive dietary supplements, and better medical care.

For the billion or so richest people in the world—including most of the population of the United States and Canada—diseases related to lifestyle or longevity tend to be much greater threats than more conventional environmental concerns such as dirty water or polluted air. Heart attacks, strokes, **cancer**, depression and hypertension, traffic accidents, trauma, and **AIDS** lead as causes of sickness and death in wealthy countries. These diseases are becoming increasingly common in the developing world as people live longer, exercise less, eat a richer diet, and use more drugs, **tobacco**, and alcohol. Epidemiologists predict that by the middle of the next century, these diseases of affluence will be leading causes of sickness and death everywhere.

Although a relatively minor cause of illness compared to the factors above, toxic or hazardous synthetic chemicals in the environment are becoming an increasing source of concern as industry uses more and more exotic materials to manufacture the goods we all purchase. There are many of these compounds to worry about. Somewhere around five million different chemical substances are known, about 100,000 are used in commercial quantities, and about 10,000 new ones are discovered or invented each year. Few of these materials have been thoroughly tested for toxicity. Furthermore, the process of predicting what our chances of exposure and potential harm might be from those re-leased into the environment remains highly controversial. **Toxins** are poisonous, which means that they react specifically with cellular components or interfere with unique physiological processes. A particular chemical may be toxic to one organism but not another, or dangerous in one type of exposure but not others. Because of this specificity, they may be harmful even in very dilute concentrations. Ricin, for instance, is a protein found in castor beans and one of the most toxic materials known. Three hundred picograms (trillionths of a gram) injected intravenously is enough to kill an average mouse. A single molecule can kill an individual cell. If humans were as sensitive as mice, a few teaspoons of this compound, divided evenly and distributed uniformly could kill everyone in the world. By the way, this points out that not all toxins are produced by industry. Many natural products are highly toxic.

Toxins that have chronic (long-lasting) or irreversible effects are of special concern. Among some important examples are neurotoxins (attack nerve cells), mutagens (cause genetic damage), teratogens (result in **birth defects**), and carcinogens (cause cancer). Many pesticides and metals such as **mercury**, **lead**, and chromium are neurotoxins. Loss of even a few critical neurons can be highly noticeable or may even be lethal making this category of great importance. Chemicals or physical factors such as radiation that damage genetic material can harm not only cells produced in the exposed individual, but also the offspring of those individuals as well.

Among the most dread characteristics of all these chronic environmental health threats are that the initial exposure may be so small or have results so unnoticeable that the victim doesn't even know that anything has happened until years later. Furthermore the results may be catastrophic and irreversible once they do appear. These are among our worst fears and are powerful reasons that we are so apprehensive about environmental contaminants. There may be no exposure—no matter how small—of some chemicals that is absolutely safe. Because of these fears, we often demand absolute protection from some of the most dread contaminants. Unfortunately, this may not be possible. There may be no way to insure that we are never exposed to any amount of some hazards. It may be that our only recourse is to ask how we can reduce our exposure or mitigate the consequences of that exposure.

In spite of the foregoing discussion of the dangers of **chronic effects** from minute exposures to certain materials or factors, not all pollutants are equally dangerous nor is every exposure an unacceptable risk. Our fear of unknown and unfamiliar industrial chemicals can lead to hysterical demands for zero exposure to risks. The fact is that life is risky. Furthermore, some materials are extremely toxic while others are only moderately or even slightly so.

This is expressed in the adage of the German physician, Paracelsus, who said in 1540 that "The dose makes the poison." It has become a basic principle of toxicology that nearly everything is toxic at some concentration but most materials have some lower level at which they present an insignificant risk. Sodium chloride (table salt), for instance, is essential for human life in small doses. If you were forced to eat a kilogram all at once, however, it would make you very sick. A similar amount injected all at once into your blood stream would be lethal.

How a material is delivered—at what rate, through which route of entry, in what form—is often as important as what the material is. The movement, distribution, and fate of materials in the environment are important aspects of environmental health. Solubility is one of the most important characteristics in deter- mining how, when, and where a material will travel through the environment and into our bodies. Chemicals that are water soluble move more rapidly and extensively but also are easier to wash off, excrete, or eliminate. Oil or fat soluble chemicals may not move through the environment as easily as water-soluble materials but may penetrate very efficiently through the skin and into tissues and organs. They also may be more likely to be concentrated and stored permanently in fat deposits in the body.

The most common route of entry into the body for many materials is through ingestion and **absorption** in the

gastrointestinal (GI) tract. The GI tract, along with the urinary system are the main routes of excretion of dangerous materials. Not surprisingly, those cells and tissues most intimately and continuously in contact with dangerous materials are among the ones most likely to be damaged. Ulcers, infections, lesions, or tumors of the mouth, esophagus, stomach, intestine, colon, kidney, bladder, and associated glands are among the most common manifestations of environmental toxins. Other common routes of entry for toxins are through the respiratory system and the skin. These also are important routes for excreting or discharging unwanted materials.

Some of our most convincing evidence about the toxicity of particular chemicals on humans has come from experiments in which volunteers (students, convicts, or others) were deliberately given measured levels under controlled conditions. Because it is now considered unethical to experiment on living humans, we are forced to depend on proxy experiments using computer models, tissue cultures, or laboratory animals. These proxy tests are difficult to interpret. We can't be sure that experimental methods can be extrapolated to how real living humans would react. The most commonly used laboratory animals in toxicity tests are rodents like rats and mice. However, different **species** can react very differently to the same compound. Of some 200 chemicals shown to be carcinogenic in either rats or mice, for instance, about half caused cancer in one species but not the other. How should we interpret these results? Should we assume that we are as sensitive as the most susceptible animal, as resistant as the least sensitive, or somewhere in between?

It is especially difficult to determine responses to very low levels of particular chemicals, especially when they are not highly toxic. The effects of random events, chance, and unknown complicating factors become troublesome, often resulting in a high level of uncertainty in predicting risk. The case of the sweetener saccharin is a good example of the complexities and uncertainties in **risk assessment**. Studies in the 1970s suggested a link between saccharin and bladder cancer in male rats. Critics pointed out that humans would have to drink 800 cans of soft drink per day to get a dose equivalent to that given to the rats. Furthermore, they argued, most people are not merely large rats.

The **Food and Drug Administration** uses a range of estimates of the probable toxicity of saccharine in humans. At current rates of consumption, the lower estimate predicts that only one person in the United states will get cancer every 1,000 years from saccharine. That is clearly inconsequential considering the advantages of reduced weight, fewer cases of diabetes, and other benefits from this sugar substitute. The upper estimate, however, suggests that 3,640 people will die each year from this same exposure. That is most certainly a risk worth worrying about.

An emerging environmental health concern with a similarly high level of uncertainty but potentially dire consequences is the disruption of endocrine hormone functions by synthetic chemicals. About ten years ago, **wildlife** biologists began to report puzzling evidence of reproductive failures and abnormal development in certain wild animal populations. Alligators in a lake in central Florida, for instance, were reported to have a 90% decline in egg hatching and juvenile survival along with feminization of adult males including abnormally small penises and lack of sperm production. Similar reproductive problems and developmental defects were reported for trout in the **Great Lakes**, seagulls in California, panthers in Florida, and a number of other species. Even humans may be effected if reports of global reduction of sperm counts and increases of hormone-dependent cancers prove to be true.

Both laboratory and field studies point to a possible role of synthetic chemicals in these problems. More than 50 chemicals, if present in high enough concentrations, are now known to mimic or disrupt the signals conveyed by naturally occurring endocrine hormones that control almost every aspect of development, behavior, immune functions, and **metabolism**. Among these chemicals are **dioxin**, polychlorinated biphenyl, and several persistent pesticides. This new field of research promises to be of great concern in the next few years because it combines dread factors of great emotional power such as undetectable exposure, threat to **future generations**, unknown or delayed consequences, and involuntary or inequitable distribution of risk.

In spite of the seriousness of the concerns expressed above, the **Environmental Protection Agency** warns that we need to take a balanced view of environmental health. The risks associated with allowable levels of certain organic solvents in drinking water or some pesticides in food are thought to carry a risk of less than one cancer in a million people in a lifetime. Many people are outraged about being exposed to this risk, yet they cheerfully accept risks thousands of times as higher from activities they enjoy such as smoking, driving a car, or eating an unhealthy diet. According to the EPA, the most important things we as individuals can do to improve our health are to reduce smoking, drive safely, eat a balanced diet, exercise reasonably, lower stress in our lives, avoid dangerous jobs, lower indoor pollutants, practice safe sex, avoid sun exposure, and prevent household accidents. Many of these factors over which we have control are much more risky than the unknown, uncontrollable, environmental hazards we fear so much.

Environmental history

Much of human history has been a struggle for food, shelter, and survival in the face of nature's harshness. Three major events or turning points have been the use of fire, the development of agriculture, and the invention of tools and machines. Each of these advances has brought benefits to humans but often at the cost of **environmental degradation**. Agriculture, for instance, increased food supplies but also caused **soil erosion**, population explosions, and support of sedentary living and urban life. It was the Industrial Revolution that gave humankind the greater power to conquer and devastate our **environment**. Jacob Bronowski called it an energy revolution, with power as the prime goal. As he noted, it is an ongoing revolution, with the fate of literally billions of people hanging on the outcome.

The Industrial Revolution, with its initial dependence on the steam engine, iron works, and heavy use of **coal**, made possible our modern lifestyle with its high consumption of energy and material resources. With it, however, has come devastating levels of air, water, land, and chemical **pollution**. In essence, environmental history is the story of the growing recognition of our negative impact upon **nature** and the corresponding public interest in correcting these abuses. Cunningham and Saigo describe four stages of **conservation** history and environmental activism: 1) pragmatic resource conservation; 2) moral and aesthetic resource preservation; 3) growing concern over the impact of pollution on health and ecosystems; and 4) global environmental citizenship.

Environmental history, like all history, is very much a study of key individuals and events. Included here are Thomas Robert Malthus, George Perkins Marsh, **Theodore Roosevelt**, and Rachel Carson. Writing at the end of the eighteenth century, Malthus was the first to develop a coherent theory of population, arguing that growth in food supply could not keep up with the much larger growth in population. Of cruel necessity, **population growth** would inevitably be limited by **famine**, pestilence, disease, or war. Modern supporters are labeled "neoMalthusians" and include notable spokespersons Paul Erlich and Lester Brown.

In his 1864 book *Man in Nature*, George Perkins Marsh was the first to attack the American myth of superabundance and inexhaustible resources. Citing many examples from Mediterranean lands and the United States, he described the devastating impact of land abuse through **deforestation** and soil erosion. Lewis Mumford called this book "the fountainhead of the conservation movement," and Stewart Udall described it as the beginning of land wisdom in this country. Marsh's work led to forest preservation and influenced President Theodore Roosevelt and his chief forester, **Gifford Pinchot**.

Effective forest and **wildlife** protection began during Theodore Roosevelt's presidency whose term of office (1901–1909) has been called "The Golden Age of Conservation." His administration established the first wildlife refuges and national forests.

At this time key differences emerged between proponents of conservation and preservation. Pinchot's policies were utilitarian, emphasizing the wise use of resources. By contrast, preservationists led by **John Muir** argued for leaving nature untouched. A key battle was fought over the **Hetch Hetchy Reservoir** in **Yosemite National Park**, a proposed water supply for San Francisco, California. Although Muir lost, the **Sierra Club** (founded in 1882) gained national prominence. Similar battles are now being waged over **petroleum** extraction in Alaska's **Arctic National Wildlife Refuge** and mining permits on federal lands, including **wilderness** areas.

Rachel Carson gained widespread fame through her battle against the indiscriminate use of pesticides. Her 1962 book *Silent Spring* has been hailed as the "fountainhead of the modern environmental movement." It has been translated into over 20 languages and is still a best seller. She argued against **pesticide** abuse and for the right of common citizens to be safe from pesticides in their own homes. Though vigorously opposed by the chemical industry, her views were vindicated by her overpowering reliance on scientific evidence, some given surreptitiously by government scientists. In effect, *Silent Spring* was the opening salvo in the battle of ecologists against chemists. Much of the current mistrust of **chemicals** stems from her work.

Several historical events are relevant to environmental history. The closing of the American frontier at the end of the nineteenth century gave political strength to the Theodore Roosevelt presidency. The 1908 White House Conference on Conservation, organized and chaired by Gifford Pinchot, is perhaps the most prestigious and influential meeting ever held in the United States.

During the 1930s, the **drought** in the American **Dust Bowl** awakened the country to the soil erosion concerns first

voiced by Marsh. The establishment of the **Soil Conservation Service** in 1935 was a direct response to this national tragedy.

In 1955, an international symposium entitled "Man's Role in Changing the Face of the Earth" was held at Princeton University. An impressive assemblage of scholars led by geographer Carl Ortwin Sauer, zoologist Marston O. Bates, and urban planner Lewis Mumford documented the history of human impact on the earth, the processes of human alteration of the environment, and the prospects for future habitability.

The *Apollo* moon voyages, especially *Apollo 8* in December 1968 and the dramatic photos taken of Earth from space, awakened the world to the concept of "spaceship earth." It was as though the entire human community gave one collective gasp at the small size and fragile beauty of this one planet we call home.

The two energy price shocks of the 1970s spawned by the 1973 Arab-Israeli War and the 1979 Iranian Islamic Revolution fundamentally altered American energy habits. Our salvation came in part from our horrific waste. Simple **energy conservation** measures and more fuel-efficient automobiles, predominantly of foreign manufacture, produced enough savings to cause a mid-1980s crash in petroleum prices. Nonetheless, many efficiencies begun during the 1970s remain.

The Montreal Accord of 1988 is notable for being the first international agreement to phase out a damaging chemical, **chlorofluorocarbons** (CFCs). This was a direct response to evidence from satellite data over **Antarctica** that chlorine-based compounds were destroying the stratospheric **ozone** shield, which provides vital protection against damaging **ultraviolet radiation**.

Key accidents and corresponding media coverage of environmental concerns have powerfully influenced public opinion. Common themes during the 1960s and 1970s included the "death of Lake Erie," the ravages of **strip mining** for coal, the confirmation of **automobile** exhaust as a key source of **photochemical smog**, destruction of the ozone layer, and the threat of global warming. The ten-hour Annenberg CPB project, *Race to Save the Planet*, is now common fare in **environmental science** telecourses.

Media coverage of specific accidents or sites has had some of the greatest impact on public awareness of environmental problems. **Oil spills** have provided especially vivid and troubling images. The wreck of the ***Torrey Canyon*** in 1967 off southern England was the first involving a supertanker, and a harbinger of even larger disasters to come, such as the ***Exxon Valdez*** spill in Alaska. The blowout of an oil well in California's Santa Barbara Channel played nightly on network television news programs. Scenes of oil-covered birds and muddy shorelines were powerful images in the battle for environmental awareness and commitment.

The **Cuyahoga River** in Cleveland was so polluted with petroleum waste that it actually caught fire twice. **Love Canal**, a forgotten chemical waste dump in Niagara Falls, New York, became the inspiration for passage of the Superfund Act, a tax on chemical companies to pay for cleanup of abandoned **hazardous waste** sites. It was also personal vindication for **Lois Marie Gibbs**, leader of the Love Canal Homeowners Association.

One **air pollution** episode in New York City was blamed for the deaths of about 300 people. In response to another in Birmingham, Alabama, a federal judge ordered the temporary shutdown of local steel mills.

The loudest alarms raised against the growing use of **nuclear power** in the U.S. were sounded by the combination of the 1979 near-meltdown at **Three Mile Island Nuclear Reactor** in Pennsylvania and the subsequent (1986) **Chernobyl Nuclear Power Station** disaster in the Ukraine.

Media coverage and growing public awareness of pollution problems, has led to widespread support for corrective legislation. A large body of such legislation was passed between 1968 and 1980. Especially notable were the **National Environmental Policy Act**, which created the **Environmental Protection Agency**, clean air and water acts, Superfund, and the **Surface Mining Control and Reclamation Act**. The latter required miners to reshape the land to near its original contour and to replace **topsoil**, both essential keys to the long-term recovery of the land.

Earlier noteworthy legislation includes the establishment in 1872 of Yellowstone as the world's first **national park**; establishment of national wildlife refuges, forests, and parks, and the agencies to oversee them; and the creation of the **Soil Conservation** Service. The **Wilderness Act** of 1964 sought to set aside government land for nondestructive uses only.

Much has been accomplished, and environmental issues now command widespread public attention. A list of books, journals, environmental organizations, and relevant government agencies now fills six pages of small print in one popular environmental textbook. Nonetheless, important challenges lie ahead in the pursuit of a quality environment that will tax environmental organizations, government policymakers, and voters.

Some key issues for the future can be grouped into the following four categories. 1) Rapidly increasing costs as control standards reach higher and higher levels. The inexpensive and easy solutions have mostly been tried. Solving the air pollution problems within the **Los Angeles basin** is a prime example of this challenge. 2) Control of **phosphates** and **nitrates** in our waterways will require increasing commitment to tertiary (or chemical) **sewage**

treatment plants. We may also find it necessary to reroute all **urban runoff** through such plants. 3) Solutions to the global warming problem, if supported by ongoing scientific research, will require alternative energy strategies, especially as large, newly emerging economies of China, India, Brazil, and other countries seek a growing share of the total energy pie. 4) There is a growing conservative trend and related hostility to environmental concerns among our younger population. Consequently, the need for meaningful **environmental education** and dialogue will only continue to increase.

Environmental impact assessment

A written analysis or process that describes and details the probable and possible effects of planned industrial or civil project activities on the **ecosystem**, resources, and **environment**. The **National Environmental Policy Act** (NEPA) first promulgated guidelines for environmental impact assessments with the intention that the environment receive proper emphasis among social, economic, and political priorities in governmental decision-making. This act required environmental impact assessments for major federal actions affecting the environment. Many states now have similar requirements for state and private activities. Such written assessments are called Environmental Impact Statements or EISs.

EISs range from brief statements to extremely detailed multi-volume reports that require many years of data collection and analysis. In general, the environmental impact assessment process requires consideration and evaluation of the proposed project, its impacts, alternatives to the project, and mitigating strategies designed to reduce the severity of adverse effects. The assessments are completed by multidisciplinary teams in government agencies and consulting firms. The experience of the United States **Army Corps of Engineers** in detailing the impacts of projects such as **dams** and waterways is particularly noteworthy, as the Corps has developed comprehensive methodologies to assess impacts of such major and complex projects. These include evaluation of direct environmental impacts as well as social and economic ramifications.

The content of the assessments generally follows guidelines in the National Environmental Policy Act. Assessments usually include the following sections:

- Background information describing the affected population and the environmental setting, including archaeological and historical features, public utilities, cultural and social values, **topography**, **hydrology**, geology and **soil**, climatology, **natural resources**, and terrestrial and aquatic communities;
- Description of the proposed action detailing its purpose, location, time frame, and relationship to other projects;
- The environmental impacts of proposed action on natural resources, ecological systems, population density, distribution and growth rate, **land use**, and human health. These impacts should be described in detail and include primary and secondary impacts, beneficial and adverse impacts, short and long term effects, the rate of recovery, and importantly, measures to reduce or eliminate adverse effects;
- Adverse impacts that cannot be avoided are described in detail, including a description of their magnitude and implications;
- Alternatives to the project are described and evaluated. These must include the "no action" alternative. A comparative analysis of alternatives permits the assessment of environmental benefits, risks, financial benefits and costs, and overall effectiveness;
- The reason for selecting the proposed action is justified as a balance between risks, impacts, costs, and other factors relevant to the project;
- The relationship between short and long term uses and maintenance is described, with the intent of detailing short and long term gains and losses;
- Reversible and irreversible impacts;
- Public participation in the process is described;
- Finally, the EIS includes a discussion of problems and issues raised by interested parties, such as specific federal, state, or local agencies, citizens, and activists.

The environmental impact assessment process provides a wealth of detailed technical information. It has been effective in stopping, altering, or improving some projects. However, serious questions have been raised about the adequacy and fairness of the process. For example, assessments may be too narrow or may not have sufficient depth. The alternatives considered may reflect the judgment of decision-makers who specify objectives, the study design, and the alternatives considered. Difficult and important questions exist regarding the balance of environmental, economic, and

other interests. Finally, these issues often take place in a politicized and highly-charged **atmosphere** that may not be amenable to negotiation. Despite these and other limitations, environmental impact assessments help to provide a systematic approach to sharing information that can improve public decision-making. *See also* Risk assessment

Other

The National Environmental Policy Act of 1969, as Amended, P.L. 91-140 (1 January 1970), amended P.L. 94-83 (9 August 1975).

Environmental Impact Statement

The **National Environmental Policy Act** (1969) made all federal agencies responsible for analyzing any activity of theirs "significantly affecting the quality of the human environment." Environmental Impact Statements (EIS) are the assessments stipulated by this act, and these reports are required for all large projects initiated, financed, or permitted by the federal government. In addition to examining the damage a particular project might have on the **environment**, federal agencies are also expected to review ways of minimizing or alleviating these adverse effects a review which can include consideration of the environmental benefits of abandoning the project altogether. The agency compiling an EIS is required to hold public hearings; it is also required to submit a draft to public review, and it is forbidden from proceeding until it releases a final version of the statement.

The NEPA has been called "the first comprehensive commitment of any modern state toward the responsible custody of its environment," and the EIS is considered one of the most important mechanisms for its enforcement. It is often difficult to identify environmental damages with remedies that can be pursued in court, but the filing of an EIS and the standards the document must meet are clear and definite requirements for which federal agencies can be held accountable. These requirements have allowed environmental groups to focus legal challenges on the adequacy of the report, contesting the way an EIS was prepared or identifying environmental effects that were not taken into account. The expense and the delays involved in defending against these challenges have often given these groups powerful leverage for convincing a company or an agency to change or omit particular elements of a project. Many environmental organizations have taken advantage of these opportunities; between 1974 and 1983, over 100 such suits were filed every year.

Although litigation over impact statements can have a decisive influence on a wide range of decisions in government and business, the legal status of these reports and the legal force of the NEPA itself are not as strong as many environmentalists believe they should be. The act does not require agencies to limit or prevent the potential environmental damage identified in an EIS. The Supreme Court upheld this interpretation in 1989, deciding that agencies are "not constrained by NEPA from deciding that other values outweigh the environmental costs." The government, in other words, is required only to identify and evaluate the adverse impacts of proposed projects; it is not required, at least by NEPA, to do anything about them. Environmentalists have long argued that environmental protection needs a stronger legal grounding than this act provides; some such as Lynton Caldwell, who was originally involved in the drafting of the NEPA, maintain that only a constitutional amendment will serve this purpose.

In addition to the controversies over what should be included in these reports and what should be done about the information, there have also been a number of debates over who is required to file them. Environmental groups have filed suit in the Pacific Northwest alleging that the government should require **logging** companies to file impact statements. And many people have observed that an EIS is not actually required of all government agencies; the U. S. Department of Agriculture, for instance, is not required to file such reports on its commodity support programs.

Impact statements have been opposed by business and industrial groups since they were first introduced. An EIS can be extremely costly to compile, and the process of filing and defending them can take years. Businesses can be left in limbo over projects in which they have already invested large amounts of money, and the uncertainties of the process itself have often stopped development before it has begun. In the debate about these statements, many advocates for business interests have pointed out that environmental regulation accounts for 23% of the 400 billion dollars the federal government spends on regulation each year. They argue that impact statements restrict the ability of the United States to compete in international markets by forcing American businesses to spend money on compliance that could be invested in research or capital improvements. Many people believe that impact statements seriously delay many aspects of economic growth, and business leaders have questioned the priorities of many environmental groups, who seem to value **conservation** over social benefits such as high-levels of employment.

In July of 1993, a judge in a federal district court ruled that the **North American Free Trade Agreement**

(NAFTA) could not be submitted to Congress for approval until the Clinton Administration had filed an EIS on the treaty. The controversy over whether an EIS should be required for NAFTA is a good example of the battle between those who want to extend the range of the EIS and those who want to limit it, as well as the practical problems with positions held by both sides.

Environmentalists fear the consequences of free trade in North America, particularly free trade with Mexico. They believe that most industries would not take any precautions about the environment unless they were forced to observe them. Environmental protection in Mexico, when it exists, is corrupt and inefficient; if NAFTA is approved by Congress, many believe that businesses in the United States will move south of the border to escape environmental regulations. This could have devastating consequences for the environment in Mexico, as well as an adverse impact on the United States economy. It is also possible that an extensive economic downturn, if perceived to be the result of such relocations, could affect the future of environmental regulation in this country as the United States begins to compete with Mexico over the incentives it can offer industry.

Opponents of the decision to require an EIS for NAFTA insist that such a document would be almost impossible to compile. The statement would have to be enormously complex; it would have to consider a range of economic as well as environmental factors, projecting the course of economic development in Mexico before predicting the impact on the environment. Extending the range of impact statements and the NEPA would cause the same expensive delays for this treaty that these statutes have caused for projects within the United States, and critics have focused mainly on the effect such an extension would have on our international competitiveness. They argue that this decision, if upheld, could have broad ramifications for American foreign policy. An EIS could be required for every treaty the government signs with another country, including negotiations over fishing rights, arms control treaties, and other trade agreements. Foreign policy decisions could then be subject to extensive litigation over the adequacy of the EIS filed by the appropriate agency. Many environmentalists would view this as a positive development, but others believe it could prevent us from assuming a leadership role in international affairs.

Carol Browner, the former chief administrator of the **Environmental Protection Agency** (EPA), announced that the agency was determined to reduce some of the difficulties of complying with environmental regulations. She was especially concerned with increasing efficiency and limiting the delays and uncertainties for business. But whatever changes she was able to make, the process of compiling an EIS will never seem cost effective to business, at least in the short term, and the controversy over these statements continues. *See also* Economic growth and the environment; Environmental auditing; Environmental economics; Environmental impact assessment; Environmental Monitoring and Assessment Program; Environmental policy; Life-cycle assessment; Risk analysis; Sustainable development

Environmental law

Environmental law has been defined as the law of planetary housekeeping. It is concerned with protecting the planet and its people from activities that upset the earth and its life-sustaining capabilities, and it is aimed at controlling or regulating human activity toward that end.

Until the 1960s, most environmental legal issues in the United States involved efforts to protect and conserve **natural resources**, such as forests and water. Public debate focused on who had the right to develop and manage those resources. In the succeeding decades, lawyers, legislators and environmental activists increasingly turned their attention to the growing and pervasive problem of **pollution**. In both instances, environmental law—a term not coined until 1969—evolved mostly from a grassroots movement that forced Congress to pass sweeping legislation, much of which contained provisions for citizen suits. As a result, the courts were thrust into a new era of judicial review of the administrative processes and of scientific uncertainty.

Initially, environmental law formed around the principles of common law, which is law created by courts and judges that rests upon a foundation of judicial precedents. However, environmental law soon moved into the arena of administrative and legislative law, which encompasses most

of today's environmental law. The following discussion looks at both areas of law, reviews some of the basic issues involved in environmental law, and outlines some landmark cases.

Generally speaking, common law is based on the notion that one party has done harm to another, in legal terms called a *tort*. There are three broad types of torts, all of which have been applied in environmental law with varying degrees of success. Trespass is the physical invasion of one's property, which has been interpreted to include situations such as **air pollution**, **runoff** of liquid wastes, or contamination of **groundwater**.

Closely associated with trespass are the torts of private and public nuisance. *Private nuisance* is interference with the use of one's property. Environmental examples include **noise pollution**, odors and other air pollution, and **water pollution**. The operation of a **hazardous waste** site fits the bill for private nuisance, where the threat of personal discomfort or disease interferes with the enjoyment of one's home. A *public nuisance* adversely affects the safety or health of the public or causes substantial annoyance or inconvenience to the public. In these situations, the courts tend to balance the plaintiff's interest against the social and economic need for the defendant's activity.

Lastly, *negligence* involves the defendant's conduct. To prove negligence it must be shown that the defendant was obligated to exercise *due care*, that the defendant breached that duty, that the plaintiff suffered actual loss or damages, and that there is a reasonable connection between the defendant's conduct and the plaintiff's injury.

These common law remedies have not been very effective in protecting the overall quality of our **environment**. The lawsuits and resulting decisions were fragmented and site specific as opposed to issue oriented. Further, they rely heavily on a level of hard scientific evidence that is elusive in environmental issues. For instance, a trespass action must be based on a somehow visible or tangible invasion, which is difficult if not impossible to prove in pollution cases. Common law presents other barriers to action. Plaintiffs must prove actual physical injury (so-called "aesthetic injuries" don't count) and a causal relationship to the plaintiff's activity, which again, is a difficult task in environmental issues.

In the early 1970s, environmental groups, aided by the media, focused public attention on the broad scope of the environmental crisis, and Congress reacted. It passed a host of comprehensive laws, including amendments to the **Clean Air Act** (CAA), the **Endangered Species Act** (ESA), the **National Environmental Policy Act** (NEPA), the **Resource Conservation and Recovery Act** (RCRA), the Toxic Substances Control Act (TSCA), and others. These laws, or statutes, are implemented by federal agencies, who gain their authority through "organic acts" passed by Congress or by executive order.

As environmental problems grew more complicated, legislators and judges increasingly deferred to the agencies' expertise on issues such as the health risk from airborne **lead**, the threshold at which a **species** should be considered endangered, or the engineering aspects of a hazardous waste incinerator. Environmental and legal activists then shifted their focus toward administrative law—challenging agency discretion and procedure as opposed to specific regulations—in order to be heard. Hence, most environmental law today falls into the administrative category.

Most environmental statutes provide for administrative appeals by which interest groups may challenge agency decisions through the agency hierarchy. If no solution is reached, the federal Administrative Procedures Act provides that any person aggrieved by an agency decision is entitled to judicial review.

The court must first grant the plaintiff "standing," the right to be a party to legal action against an agency. Under this doctrine, plaintiffs must show they have been injured or harmed in some way. The court must then decide the level of judicial review based on one of three issues—interpretation of applicable statutes, factual basis of agency action, and agency procedure—and apply a different level of scrutiny in each instance.

Generally, courts are faced with five basic questions when reviewing agency action: Is the action or decision constitutional? Did the agency exceed its statutory authority or jurisdiction? Did if follow legal procedure? Is the decision supported by substantial evidence in the record? Is the decision arbitrary or capricious? Depending on the answers, the court may uphold the decision, modify it, remand or send it back to the agency to redo or reverse it.

By far the most important statute that cracked open the administrative process to judicial review is NEPA. Passed in 1969, the law requires all agencies to prepare an **Environmental Impact Statement** (EIS) for all major federal actions, including construction projects and issuing permits. Environmental groups have used this law repeatedly to force agencies to consider the environmental consequences of their actions, attacking various procedural aspects of EIS preparation. For example, they often claim that a given agency failed to consider alternative actions to the proposed one, which might reduce environmental impact.

In filing a lawsuit, plaintiffs might seek an injunction against a certain action, say, to stop an industry from dumping toxic waste into a river, or stop work on a public project such as a dam or a timber sale that they claim causes environmental damage. They might seek compensatory damages to make up for a loss of property or for health costs, for instance,

and punitive damages, money awards above and beyond repayment of actual losses.

Boomer v. Atlantic Cement Co. (1970) is a classic common law nuisance case. The neighbors of a large cement plant claimed they had incurred property damage from dirt, **smoke** and vibrations. They sued for compensatory damages and to enjoin or stop the polluting activities, which would have meant shutting down the plant, a mainstay of the local economy. The New York court rejected a long-standing practice and denied the injunction. Further, in an unusual move, the court ordered the company to pay the plaintiffs for present *and* future economic loss to their properties. A dissenting judge said the rule was a virtual license for the company to continue the nuisance so long as it paid for it.

Sierra Club v. Morton (1972) opened the way for environmental groups to act on behalf of the public interest, and of **nature**, in the courtroom. The **Sierra Club** challenged the U.S. Forest Service's approval of Walt Disney Enterprises' plan to build a $35 million complex of motels, restaurants, swimming pools and ski facilities that would accommodate up to 14,000 visitors daily in Mineral King Valley, a remote, relatively undeveloped national game refuge in the Sierra Nevada Mountains of California. The case posed the now-famous question: Do trees have standing? The Supreme Court held that the Sierra Club was not "injured in fact" by the development and therefore did not have standing. The Sierra Club reworded its petition, gained standing and stopped the development.

Citizens to Preserve Overton Park v. Volpe (1971) established the so-called "hard look" test to which agencies must adhere even during informal rule making. It opened the way for more intense judicial review of the administrative record to determine if an agency had made a "clear error of judgment." The plaintiffs, local residents and conservationists, sued to stop the U.S. Department of **Transportation** from approving a six-lane interstate through a public park in Memphis, Tennessee. The court found that Secretary Volpe had not carefully reviewed the facts on record before making his decision and had not examined possible alternative routes around the park. The case was sent back to the agency, and the road was never built.

Tennessee Valley Authority v. Hill (1978) was the first major test of the **Endangered Species** Act and gained the tiny **snail darter** fish fame throughout the land. The Supreme Court authorized an injunction against completion of a multi-million dollar dam in Tennessee because it threatened the snail darter, an endangered species. The court balanced the act against the money that had already been spent and ruled that Congress's intent in protecting endangered species was paramount.

Just v. Marinette County (1972) involved **wetlands**, the **public trust** doctrine and private property rights. The plaintiffs claimed that the county's ordinance against filling in wetlands on their land was unconstitutional, and that the restrictions amounted to taking their property without compensation. The county argued it was exercising its normal police powers to protect the health, safety and welfare of citizens by protecting its **water resources** through zoning measures. The Wisconsin appellate court ruled in favor of the defendant, holding that the highest and best use of land does not always equate to monetary value, but includes the natural value. The opinion reads, "...we think it is not an unreasonable exercise of that [police] power to prevent harm to public rights by limiting the use of private property to its natural uses."

Although some progress was made in curbing **environmental degradation** through environmental law in the 1970s, environmental legislation was significantly weakened by the Supreme Court in the 1980s.

Environmental Law Institute

Environmental Law Institute (ELI) is an independent research and education center involved in developing environmental laws and policies at both national and international levels. The institute was founded in 1969 by the Public Law Education Institute and the Conservation Foundation to conduct and promote research on environmental law. In the ensuing years it has maintained a strong and effective presence in forums ranging from college courses to law conferences. For example, ELI has organized instructional courses at universities for both federal and non-governmental agencies. In addition, it has sponsored conferences in conjunction with such bodies as the American Bar Association, the American Law Institute, and the Smithsonian Institute.

Within the field of environmental law, ELI provides a range of educational programs and services. In 1991, for instance, the institute helped develop an environmental law course for practicing judges in the New England area. Through funding and endowments, the institute has since managed to expand this particular judicial education program into other regions. A similar program enables ELI to offer

training courses to federal judges currently serving in district, circuit, and even bankruptcy courts.

ELI also offers various workshops to the general public. In New Jersey, the institute provided a course designed to guide citizens through the state's environmental laws and thus enable them to better develop pollution-prevention programs in their communities. Broader **right-to-know** guidance has since been provided—in collaboration with the **World Wildlife Fund**—at the international level.

ELI's endeavors at the federal level include various interactions with the **Environmental Protection Agency** (EPA). The two groups worked together to develop the National **Wetlands** Protection Hotline, which answers public inquiries on wetlands protection and regulation, and to assess the dangers of exposure to various pollutants.

Since its inception, ELI has evolved into a formidable force in the field of environmental law. In 1991, it drafted a statute to address the continuing problem of **lead poisoning** in children. The institute has also worked—in conjunction with federal and private groups, including scientists, bankers, and even realtors—to address health problems attributable to **radon** gas.

ELI has compiled and produced several publications. Among the leading ELI books are *Law of Environmental Protection*, a two-volume handbook (updated annually) on **pollution control** law, and *Practical Guide to Environmental Management*, a resource book on worker health and safety. In addition, ELI has worked with the EPA in producing *Environmental Investments: The Cost of a Clean Environment*. The institute's principal periodical is *Environmental Law Reporter*, which provides analysis and coverage of topics ranging from courtroom decisions to regulation developments. ELI also publishes *Environmental Forum*—a policy journal intended primarily for individuals in environmental law, policy, and management—and *National Wetlands Newsletter*, which reports on ensuing developments—legal, scientific, regulatory—related to wetlands management.

Environmental liability

Environmental liability refers primarily to the civil and criminal responsibility in the environmental issues of hazardous substances that threaten to endanger public health. Compliance with the standards issued by the U.S. **Environmental Protection Agency** (EPA) became a major issue following the December 11, 1980 enactment by Congress of the original **Comprehensive Environmental Response, Compensation, and Liability Act** (CERCLA). In 1986, the **Superfund Amendments and Reauthorization Act** (SARA) provided an amendment to CERCLA. The initial legislation created a tax on chemical and **petroleum** companies, and gave the federal government authority to handle the releases or threatened releases of the **hazardous waste**. That tax created $1.6 billion over the first five years of the act, put into a trust fund that would cover the costs of cleaning up abandoned or uncontrolled hazardous waste sites. When "Superfund" was created, changes to the original legislation, as well as additions, were made that reflected the experience gained from the first years of administering the program. It also raised the trust fund to $8.5 billion.

The complex issue of liability was made more complex following 1986 when regulations increased state involvement, and encouraged greater citizen participation in the decisions of site cleanup. In addition to the civil liability of claims due to federal, state, and local governments, a possibility of criminal liability emerged as a matter of particular concern. As those who might be responsible, CERCLA defines four categories of individuals and corporations against whom judgment could be rendered, referred to as potentially responsible parties (PRPs):

- current owners or operators of a specific piece of real estate
- past owners if they owned or operated the property at the time of the hazardous contamination
- generators and possessors of hazardous substances who arranged for disposal, treatment, or transport
- certain transporters of hazardous substances

In acting under EPA-expanded powers, some states have provided exemptions from liability in certain cases. For example, the state of Wisconsin has provided that the person responsible for the **discharge** of a hazardous substance is the one who is required to report it, investigate, it and clean up the contamination. According to Wisconsin Department of **Natural Resources** information, the state defines the responsible person as the one who "causes, possesses, or controls" the contamination—the one who owns the property with a contaminant discharge or owns a container that has ruptured. Other Wisconsin exemptions include limiting liability for parties who voluntarily remediate contaminated property; limiting liability for lenders and representatives, such as banks, credit unions, mortgage bankers, and similar financial institutions, or insurance companies, pension funds or government agencies engaged in secured lending; limiting liability for local government units; and, limiting liability for property affected by off-site discharge.

Courts have also acted in finding persons responsible not specifically listed as PRPs:

- lessees of contaminated property
- lessors of the contaminated property for contamination caused by their lessees
- Landlords and lessees for the contamination cause by their sub-lessees
- corporate officers in their personal capacity
- shareholders
- parent corporations liable for their subsidiaries
- trustees and personal representatives personally liable for contaminated property owned by a trust or estate
- successor corporation
- donees
- lenders who foreclose on and subsequently manage contaminated property

In an environmentally aware, health-conscious society, both in America and throughout the world, environmental liability continues into the early twenty-first century to be a matter of grave concern not only with land, but also in maritime issues.

Environmental literacy and ecocriticism

Environmental literacy and ecocriticism refer to the work of educators, scholars, and writers to foster a critical understanding about environmental issues. Environmental literacy includes educational materials and programs designed to provide lay citizens and students with a broad understanding of the relationship between humans and the natural world, borrowing from the fields of science, politics, economics, and the arts. Environmental literacy also seeks to develop the knowledge and skills citizens and students may need to identify and resolve environmental crises, individually or as a group. Ecocriticism is a branch of literary studies that offers insights into the underlying philosophies in literature that address the theme of **nature** and have been catalysts for change in public consciousness concerning the **environment**.

Americans have long turned to literature and popular culture to develop, discuss, and communicate various ideals about the natural world and their relationship to how Americans see themselves and function together. This literature has also made people think about the idea of progress: what constitutes advancement in culture, what are the goals of a healthy society, and how nature would be considered and treated by such a society. In contemporary times, the power and **visibility** of modern media in influencing these debates is also widely recognized. Given this trend, understanding how these forms of communication work and developing them further to broaden public participation, which is a task of environmental literacy and ecocriticism, is vital to the environmental movement.

Educators and ecocritics take diverse approaches to the task of raising consciousness about environmental issues, but they share a collective concern for the global environmental crisis and begin with the understanding that nature and human needs require rebalancing. In that, they become emissaries, as writer Barry Lopez suggests in *Orion* magazine, who have to "reestablish good relations with all the biological components humanity has excluded from its moral universe." For Lopez, as with many generations of nature writers, including **Henry David Thoreau**, **John Muir**, Edward Abbey, and Terry Tempest Williams, and Annie Dilliard, the lessons to be imparted are learned from long experience with and observation of nature. Lopez suggests another pervasive theme, that observing the ever-changing natural world can be a humbling experience, when he writes of "a **horizon** rather than a boundary for knowing, toward which we are always walking."

The career of Henry David Thoreau was one of the most influential and early models for being a student of the natural world and for the development of an environmental awareness through attentive participation within nature. Thoreau also made a fundamental contribution to American's identification with the ideals of individualism and self-sufficiency. His most important work, *Walden*, was a book developed from his journal written during a two-and-a-half-year experiment of living alone and self-sufficiently in the woods near Concord, Massachusetts. Thoreau describes his process of education as an awakening to a deep sense of his interrelatedness to the natural world and to the sacred power of such awareness. This is contrasted to the human society from which he isolated himself, of whose **utilitarianism**, materialism, and consumerism he was extremely critical.

Thoreau famously writes in *Walden*: "I went to the woods because I wished to live deliberately, to front only the essential facts of life, and see if I could not learn what it had to teach, and not, when I came to die, discover that I had not lived." For Thoreau, living with awareness of the greater natural world became a matter of life and death.

Many educators have also been influenced by two founding policy documents, created by commissions of the United Nations, in the field of environmental literacy. The Belgrade Charter (UNESCO-UNEP, 1976) and the Tbilisi Declaration (**UNESCO**, 1978) share the goal "to develop a world population that is aware of, and concerned about, the environment and its associated problems." Later governmental bodies such as the Brundtland Commission (Brundtland, 1987), the United Nations Conference on Environment and Development in Rio (UNCED, 1992), and the Thessaloniki Declaration (UNESCO, 1997) have built on these ideas.

One of the main goals of environmental literacy is to provide learners with knowledge and experience to assess the health of an ecological system and to develop solutions to problems. Models for environmental literacy include curriculums that address key ecological concepts, provide hands-on opportunities, foster collaborative learning, and establish an **atmosphere** that strengthens a learner's belief in responsible living. Environmental literacy in such programs is seen as more than the ability to read or write. As in nature writing, it is also about a sensibility that views the natural world with a sense of wonder and experiences nature through all the senses. The element of direct experience of the natural world is seen as crucial in developing this sensibility. The Edible Schoolyard program in the Berkeley, California, school district, for example, integrates an organic garden project into the curriculum and lunch program, where students become involved in the entire process of farming, while learning to grow and prepare their own food. The program aims to promote participation and awareness to the workings of the natural world, and also to awaken all the senses to enrich the process of an individual's development.

Public interest in **environmental education** came to the forefront in the 1970s. Much of the impetus as well as the funding for integrating environmental education into school curriculums comes from non-profit foundations and educators' associations such as the Association for Environmental and Outdoor Education, the Center for Ecoliteracy, and The Institute for Earth Education. In 1990, the United States Congress created the National Environmental Education and Training Foundation (NEETF) whose efforts include expanding environmental literacy among adults and providing funding opportunities for school districts to advance their environmental curriculums. The National Environmental Education Act of 1990 directed the **Environmental Protection Agency** (EPA) to provide national leadership in the environmental literacy arena. To that end, the EPA established several initiatives including the Environmental Education Center as a resource for educators, and the Office of Environmental Education, which provides grants, training, fellowships, and youth awards.

The Public Broadcasting System also plays an active role in the promotion of environmental literacy as evidenced by the partnership of the Annenberg Foundation and the Corporation for Public Broadcasting to create and disseminate educational videos for students and teachers, and grant programs such as that sponsored by New York's Channel 13/WNET Challenge Grants.

A common thread woven through these organizations is a definition of environmental learning that goes beyond simple learning to an appreciation of nature. However, appreciation is measured differently by each organization and segments of the American population differ on which aspects of the environment should be preserved. At the end of the 1990s, the George C. Marshall Institute directed an independent commission to study whether the goals of environmental education were being met. The Commission's 1997 report found that curricula and texts vary widely on many environmental concepts, including what constitutes **conservation**. Although thirty-one states have academic standards for environmental education, a national cohesiveness is lacking.

Thus, the main challenges to environmental literacy are the lack of unifying programs that would bring together the many approaches to environmental education, and the fact that there is inconsistent support for these programs from the government and public school system. Observers of environmental literacy movements suggest that the new perspectives that learners gain may often be at odds with the concerns and ethics of mainstream society, issues that writers such as Thoreau grappled with. For instance, consumerism and conservationism may be at opposite ends of the spectrum of how people interact with the natural world and its resources. To be effective, literacy initiatives must address these dilemmas and provide tools to solve them. Environmental literacy is thus about providing new ways of seeing the world, about providing language tools to address these new perceptions, and to provide ethical frameworks through which people can make informed choices on how to act.

Ecocriticism develops the tools of literary criticism to understand how the relationship of humans to nature is addressed in literature, as a subject, character, or as a component of the setting. Ecocritics also highlight the ways in which literature is a vehicle to create environmental consciousness. For critic William Rueckert, the scholar who coined the term *ecocriticism* in 1978, poetry and literature are the "verbal equivalent of fossil fuel, only renewable,"

through which abundant energy is transferred between nature and the reader.

Ecocritics highlight aspects of nature described in literature, whether frontiers, rivers, regional ecosystems, cities, or **garbage**, and ask what the purposes of these descriptions are. Their interests have included understanding how historical movements such as the Industrial Revolution have changed the relationship between human society and nature, giving people the false illusion that they can completely control nature, for instance. Ecocriticism also brings together perspectives from various academic disciplines and draws attention to their shared purposes. Studies in **ecology** and cellular biology, for example, echo the theme of interconnectedness of the individual and the natural world seen in poetry, by demonstrating how the life of all organisms is dependent upon their on-going interactions with the environment around them.

Although nature writers have expressed their philosophies of nature and reflected on their modes of communication since the nineteenth century, as a self-conscious practice, ecocriticism's history did not began until the late 1970s. By the 1990s, it had gained wide currency. In his 1997 article "Wild Things," published in *Utne Reader*, Gregory McNamee notes that courses in environmental literature are available at colleges across the nation and that "'ecocritcism' has become something of an academic growth industry." In 1992, the Association for the Study of Literature and Environment (ASLE) was founded with the mission "to promote the exchange of ideas and information about literature and other cultural representations that consider that human relationships with the natural world".

Nature's role in theatre and film are also popular ecocriticism topics for academic study in the form of seminars on, for example, The Nature of Shakespeare, and suggested lists of commercial films for class discussion that include *Chinatown*, *Deliverance*, *The China Syndrome*, *Silkwood*, *A Civil Action* and *Jurassic Park*.

Ecocritics Carl Herndl and Stuart Brown suggest that there are three underlying philosophies in evaluating nature in modern society. The language used by institutions that make government policies usually regards nature as a resource to be managed for greater social welfare. This is described as an ethnocentric perspective, which begins with the idea that one opinion or way of looking at the world is superior to others. Thus, the benefits of environmental issues are always measured against various political and social interests, and not seen as important simply in themselves.

Another viewpoint is the anthropocentric perspective, wherein human perspectives are central in the world and are the ultimate source of meaning. The specialized language of the sciences, which treats nature as an object of study, is an example of this. The researcher is seen as existing outside of or above nature, and science is grounded on the faith that humans can come to know all of nature's secrets.

In contrast, poetry often describes nature in terms of its beauty and emotional and spiritual power. This language sees man as part of the natural world and seeks to harmonize human values and actions with a respect for nature. This is the ecocentric perspective, which means putting nature and ecology as the central viewpoint when considering the various interactions in the world, including human ones. That is, this perspective acknowledges that humans are a part and parcel of nature and ultimately depend upon the ecology's living and complex interactions for survival.

Scholars make the distinction between environmental writing and other kinds of literature that use images of nature in some fashion or another. Environmental writing explores at length ecocentric perspectives. They include discussions about human ethical responsibility towards the natural world, such as in Aldo Leopold's *A Sand County Almanac*, considered one of the best explorations of **environmental ethics**. Many ecocritics also share a concern for the environment, and one aim of eco-criticism is to raise awareness within the literary world about the environmental movement and nature-centered perspectives in understanding human relationships and cultural practices.

In *Silent Spring*, a major text in the field of environmental literacy and ecocriticism, Rachel Carson writes that society faces two choices: to travel as we now do on a superhighway at high speed but ending in disaster, or to walk the less traveled "other road" which offers the chance to preserve the earth. The challenge of ecocriticism is to spread the word of the "other road," and to simultaneously offer constructive criticism to the environmental movement from within.

Environmental monitoring

Environmental monitoring detects changes in the health of an **ecosystem** and indicates whether conditions are improving, stable, or deteriorating. This quality, too large to gauge as a whole, is assessed by measuring indicators, which represent more complex characteristics. The concentration of **sulfur dioxide**, for example, is an indicator that reflects the presence of other air pollutants. The abundance of a predator indicates the health of the larger **environment**. Other indicators include **metabolism**, population, community, and landscape. All changes are compared to an ideal, pristine ecosystem. The SER (stressor-exposure-response) model, a simple but widely used tool in environmental monitoring, classifies indicators as one of three related types:

- Stressors, which are agents of change associated with physical, chemical, or biological constraints on environmental processes and integrity. Many stressors are caused by humans, such as **air pollution**, the use of pesticides and other toxic substances, or **habitat** change caused by forest clearing. Stressors can also be natural processes, such as **wildfire**, hurricanes, volcanoes, and **climate** change.
- Exposure indicators, which link a stressor's intensity at any point in time to the cumulative dose received. Concentrations or accumulations of toxic substances are exposure indicators; so are **clear-cutting** and urbanization.
- Response indicators, which shows how organisms, communities, processes, or ecosystems react when exposed to a stressor. These include changes in physiology, productivity, or **mortality**, as well as changes in **species** diversity within communities and in rates of **nutrient** cycling.

The SER model is useful because it links ecological change with exposure to **environmental stress**. Its effectiveness is limited, however. The model is a simple one, so it cannot be used for complex environmental situations. Even with smaller-scale problems, the connections between stressor, exposure, and response are not understood in many cases, and additional research is required.

Environmental monitoring programs are usually one of two types, extensive or intensive. Extensive monitoring occurs at permanent, widely spaced locations, sometimes using remote-sensing techniques. It provides an overview of changes in the ecological character of the landscape, often detecting regional trends. It measures the effects of human activities like farming, forestry, mining, and urbanization. Information from extensive monitoring is often collected by the government to determine such variables as water and **air quality**, to calculate allowable forest harvests, set bag limits for **hunting** and fishing, and establish the production of agricultural commodities.

Extensive monitoring usually measures stressors (such as emissions) or exposure indicators (concentration of pollutants in the air). Response indicators, if measured at all in these programs, almost always have some economic importance (damage to forest or agricultural crops). Distinct species or ecological processes do not have economic value and are not usually assessed in extensive-monitoring programs, even though these are the most relevant indicators of **ecological integrity**.

Intensive monitoring is used for detailed studies of structural and functional **ecology**. Unlike extensive monitoring, a relatively small number of sites provide information on stressors such as climate change and **acid rain**. Intensive monitoring is also used to conduct experiments in which stressors are manipulated and the responses studied, for example by acidifying or fertilizing lakes, or by conducting forestry over an entire **watershed**. This research, aimed at understanding the dynamics of ecosystems, helps develop ecological models that distinguish between natural and **anthropogenic** change.

Support for ecological monitoring of either kind has been weak, although more countries are beginning programs and establishing networks between monitoring sites. The United States has founded the Long-Term Ecological Research (LTER) network to study extensive ecosystem function, but little effort is directed toward understanding environmental change. The **Environmental Monitoring and Assessment Program** (EMAP) of the **Environmental Protection Agency** (EPA) studies intensive environmental change, but its activities are not integrated with LTER. In

comparison, an ecological-monitoring network being designed by the government of Canada to study changes in the environment will integrate both extensive and intensive monitoring.

Communication between the two types of monitoring is important. Intensive information provides a deeper understanding of the meaning of extensive-monitoring indicators. For example, it is much easier to measure decreases in surface-water **pH** and alkalinity caused by **acid** rain than to monitor resulting changes in fish or other biological variables. These criteria can, however, be measured at intensive-monitoring sites, and their relationships to pH and alkalinity used to predict effects on fish and other **fauna** at extensive sites where only pH and alkalinity are monitored.

The ultimate goal of environmental monitoring is to measure, anticipate, and prevent the deterioration of ecological integrity. Healthy ecosystems are necessary for healthy societies and sustainable economic systems. Environmental monitoring programs can accomplish these goals, but they are expensive and require a substantial commitment by government. Much has yet to be accomplished.

Environmental Monitoring and Assessment Program

The **Environmental Monitoring** and Assessment Program (EMAP), established in 1990 by the **Environmental Protection Agency** (EPA), is a federal project designed to create a continually updated survey of ecological resources in the United States. This comprehensive list monitors and links resource data from several U.S. agencies, including the **National Oceanic and Atmospheric Administration**, the **Fish and Wildlife Service**, and the **U.S. Department of Agriculture**.

Research from the program is intended to illustrate changes in specific ecosystems in the U.S. and to determine if those changes could have resulted from "human-induced stress."

Environmental policy

Strictly, an environmental policy can be defined as a government's chosen course of action or plan to address issues such as **pollution**, **wildlife** protection, **land use**, energy production and use, waste generation, and waste disposal. In reality, the way a particular government handles environmental problems is most often not a result of a conscious choice from a set of alternatives. More broadly, then, a government's environmental policy may be characterized by examining the overall orientation of its responses to environmental challenges as they occur, or by defining its policy as the sum of plans for, and reactions to, environmental issues made by any number of different arms of government.

A society's environmental policy will be shaped by the actions of its leaders in relation to the five following questions:

- Should government intervene in the regulation of the **environment** or leave resolution of environmental problems to the legal system or the market?
- If government intervention is desirable, at what level should that intervention take place? In the United States, for example, how should responsibility for resolution of environmental problems be divided between and among federal, state and local governments and who should have *primary* responsibility?
- If government intervenes at some level, how much protection should it give? How safe should the people be and what are the economic trade-offs necessary to ensure that level of safety?
- Once environmental standards have been set, what are the methods to attain them? How does the system control the sources of environmental destruction so that the environmental goals are met?
- Finally, how does the system monitor the environment for compliance to standards and how does it punish those who violate them?

Policy in the United States

The United States has no single, overarching environmental policy and its response to environmental issues—subject to conflicting political, corporate and public influence, economic limitation and scientific uncertainty—is

rarely monolithic. American environmental policies are an amalgamation of Congressional, state and local laws, regulations and rules formulated by agencies to implement those laws, judicial decisions rendered when those rules are challenged in court, programs undertaken by private businesses and industry, as well as trends in public concerns.

In Congress, many environmental policies were originally formed by what are commonly known as "iron triangles." These involve three groups of actors who form a powerful coalition: the Congressional committee with jurisdiction over the issue; the relevant federal agency handling the problem; and the interest group representing the particular regulated industry. For example, the key actors in forming policy on **clear-cutting** in the national forests are the House subcommittee on Forests, Family Farms and Energy, the U.S. **Forest Service** (USFS), and the National Forest Products Association, which represents many industries dependent on timber.

For more than a century, **conservation** and environmental groups worked at the fringes of the traditional "iron triangle." Increasingly, however, these public interest groups—which derived their financial support and sense of mission from an increasing number of citizen members—began gaining more influence. Scientists, whose studies and research today play a pivotal role in decision-making, also began to emerge as major players.

The Watershed years

Catalyzed by vocal, energetic activists and organizations, the emergence of an "environmental movement" in the late 1960s prompted the government to grant environmental protection a greater priority and **visibility**. 1970, the year of the first celebration of **Earth Day**, saw the federal government's landmark passage of the **Clean Air Act** and the **National Environmental Policy Act**, as well as Richard Nixon's creation of an **Environmental Protection Agency** (EPA) which was given the control of many environmental policies previously administered by other agencies. In addition, some of the most serious problems such as DDT and **mercury** contamination began to be addressed between 1969 and 1972. Yet, environmental policies in the 1970s developed largely in an adversarial setting pitting environmental groups on one side and the traditional iron triangles on the other.

The first policies that came out of this era were designed to clean up visible pollution—clouds of industrial soot and dust, detergent-filled streams and so forth—and employed "end-of-pipe" solutions to target point sources, such as **wastewater discharge** pipes, smokestacks, and other easily identifiable emitters.

An initial optimism generated by improvements in air and **water quality** was dashed by a series of frightening environmental episodes at **Times Beach**, Missouri, Three Mile Island, **Love Canal**, New York and other locations. Such incidents (as well as memory of the devastation caused by the recently-banned DDT) shifted the focus of public concern to specific toxic agents. By the early 1980s, a fearful public led by environmentalists had steered governmental policy toward tight regulation of individual, invisible toxic substances—dioxin, PCBs and others—by backing measures limiting emissions to within a few **parts per million**. Without an overall governmental framework for action, the result has been a multitude of regulations and laws that address specific problems in specific regions that sometimes conflict and often fail to protect the environment in a comprehensive manner. "It's been reactionary, and so we've lost the integration of thought and disciplines that is essential in environmental policy making," says **Carol Browner**, administrator of the U.S. EPA.

One example of policy-making gone awry is the 1980 **Comprehensive Environmental Response, Compensation and Liability Act** (CERCLA), or *Superfund* toxic waste program. The law grew as much out of the public's perception and fear of toxic waste as it did from crude scientific knowledge of actual health risks. Roughly $2 billion dollars a year has been spent cleaning up a handful of the nation's worst toxic sites to near pristine condition. EPA officials now believe the money could have been better spent cleaning up *more* sites, although to a somewhat lesser degree.

Current trends in environmental policy

Today, governmental bodies and public interest groups are drawing back from "micro management" of individual **chemicals**, individual **species** and individual industries to focus more on the interconnections of environmental systems and problems. This new orientation has been shaped by several (sometimes conflicting) forces, including:

- industrial and public **resistance** to tight regulations fostered by fears that such laws impact employment and economic prosperity; (2) financial limitations that prevent government from carrying out tasks related to specific contaminants, such as cleaning up waste sites or closely monitoring toxic discharges; (3) a perception that large-scale, global problems such as the **greenhouse effect**, **ozone layer depletion**, **habitat** destruction and the like should receive priority; (4) the emergence of a "preventative" orientation on the part of citizen groups that attempts to link economic prosperity with environmental goals. This approach emphasizes **recycling**, efficiency, and environmental technology and stresses the prevention of problems rather than their **remediation** after they reach a critical stage. This strategy also marks an attempt by some citizen organizations to a more conciliatory stance with industry and government.

This new era of environmental policy is underscored by the election of Bill Clinton and Albert Gore, who made the environment a cornerstone of their campaign. In all likelihood, the Clinton administration will transform the

EPA into the cabinet-level position of Department of the Environment, giving the agency more stature and power. The EPA, the USFS and other federal environmental agencies have announced a new "ecosystem" approach to resource management and **pollution control**. In a bold first move, Congressional Democratic leaders are simultaneously reviewing four major environmental statutes (the **Resource Conservation and Recovery Act** [RCRA], **Clean Water Act** [CWA], **Endangered Species Act** [ESA] and Superfund) in the hopes of integrating the policies into a comprehensive program. *See also* Pollution Prevention Act

Environmental Protection Agency (EPA)

The Environmental Protection Agency (EPA) was established in July of 1970, a landmark year for environmental concerns, having been preceded by the passing of the **National Environmental Policy Act** in January and the first **Earth Day** celebrations in April. President Richard Nixon and Congress, working together in response to the growing public demand for cleaner air, land, and water, sought to create a new agency of the federal government structured to make a coordinated attack on the pollutants that endanger human health and degrade the **environment**. The EPA was charged with repairing the damage already done to the environment and with instituting new policies designed to maintain a clean environment.

The EPA's mission is "to protect human health and to safeguard the natural environment." At the time the EPA was formed, at least fifteen programs in five different agencies and cabinet-level departments were handling **environmental policy** issues. For the EPA to work effectively, it was necessary to consolidate the environmental activities of the federal government into one agency. **Air pollution control**, solid **waste management**, radiation control, and the drinking water program were transferred from the U.S. Department of Health, Education and Welfare (currently known as the **U.S. Department of Health and Human Services**). The **water pollution** control and pesticides research programs were acquired from the **U.S. Department of the Interior**. Registration and regulation of pesticides was transferred from the **U.S. Department of Agriculture**, and the responsibility for setting tolerance levels for pesticides in food was acquired from the **Food and Drug Administration**. The EPA also took over from the **Atomic Energy Commission** the responsibility for setting some environmental radiation protection standards and assumed some of the duties of the Federal Radiation Council. For some environmental programs, the EPA works with other agencies: for example, the United States Coast Guard and the EPA work together on flood control, shoreline protection, and **dredging** and filling activities. And, since most state governments in the United States have their own environmental protection departments, the EPA delegates the implementation and enforcement of many federal programs to the states.

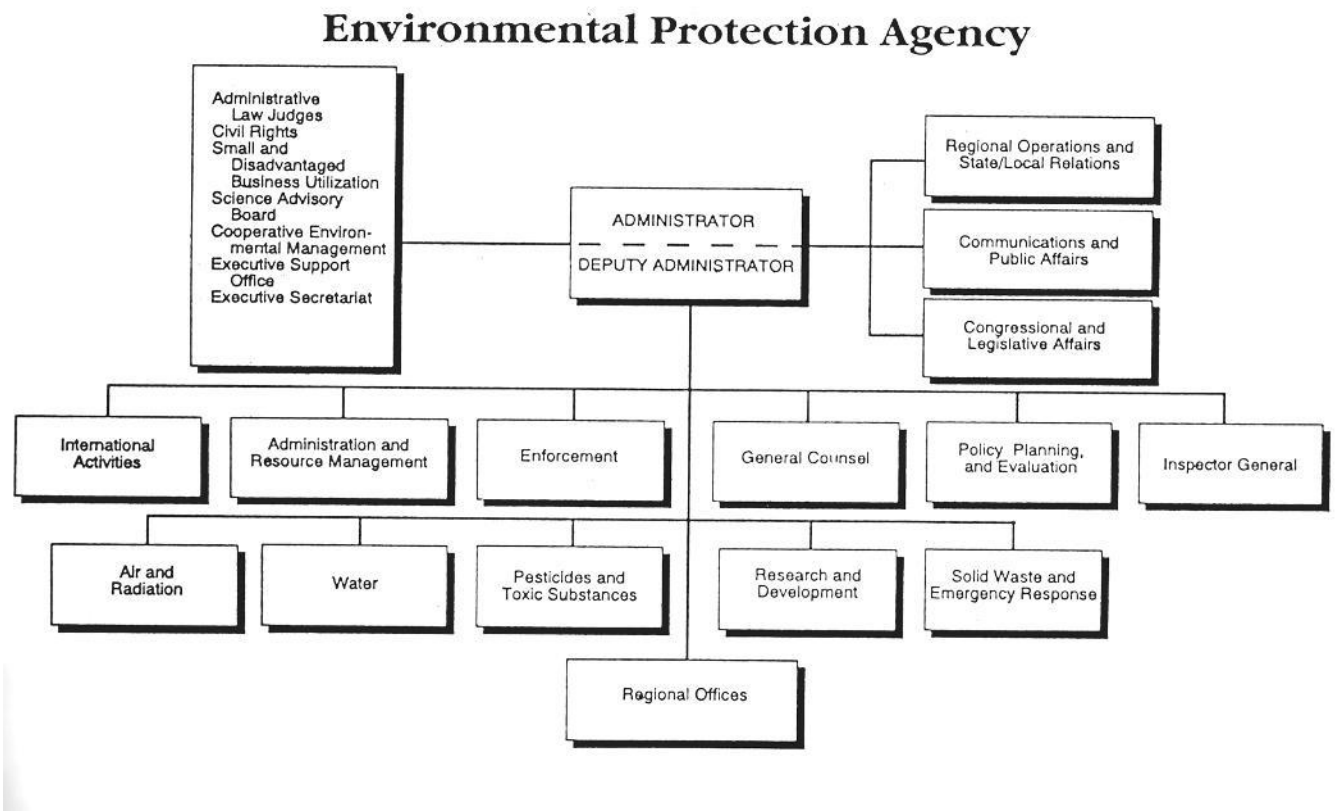
The EPA's headquarters is in Washington DC, and there are ten EPA regional offices and field laboratories. The main office develops national environmental policy and programs, oversees the regional offices and laboratories, requests an annual budget from Congress, and conducts research. The regional offices implement national policies, oversee the environmental programs that have been delegated to the states, and review Environmental Impact Statements for federal actions. The field laboratories conduct research, the data from which are used to develop policies and provide analytical support for monitoring and enforcement of EPA regulations, and for the administration of permit programs.

The administrator of the EPA is appointed by the President, subject to approval by the Senate. The same procedure is used to appoint a deputy administrator, who assists the administrator, and nine assistant administrators, who oversee programs and support functions. Other posts include the chief financial officer, who manages the EPA' budget and funding operations, the inspector general, who is respon-

sible for investigating environmental crimes, and a general counsel, who provides legal support.

In addition to the administrative offices, the EPA is organized into the following program offices: The Office of Air and Radiation, the **American Indian Environmental Office**, the Office of Enforcement and Compliance Assurance, the Office of Environmental Justice, the Office of Environmental Information, the History Office, the Office of International Affairs, the Office of Prevention, Pesticides and Toxic Substances, the Office of Research and Development, the Science Policy Council, the office of **Solid Waste** and Emergency Response, and the Office of Water.

The current EPA Administrator, elected by President George W. Bush, is Christie Whitman, formerly Governor of New Jersey, who was sworn in on January 31, 2001. Whitman's official administrative philosophy is that environmental goals are compatible with and are connected to economic goals, and that relationships between citizens, policy makers, and private sector must be strengthened. The nomination of Linda J. Fisher to the post of EPA Deputy Administrator was confirmed by the U.S. Senate on May 24, 2001. Fisher, who formerly practiced law in Washington DC and has served as Vice President and Corporate Officer at the Monsanto Co. in St. Louis MO, is Whitman' top managerial and policy assistant.



One of the major activities of the EPA is the management of Superfund sites. For many years, uncontrolled dumping of hazardous chemical and industrial wastes in abandoned warehouses and landfills continued without concern for the potential impact on public health and the environment. Concern over the extent of the hazardous-waste-site problem led Congress to establish the Superfund Program in 1980 to locate, investigate, and clean up the worst such sites. The EPA' Office of Emergency and Remedial Response (OERR) oversees management of the program in cooperation with individual states. When a hazardous-waste site is discovered, the EPA is notified. The EPA makes a preliminary assessment of the site and gives a numerical score according to **Hazard Ranking System** (HRS), which determines whether the site is placed on the **National Priorities List** (NPL). As of May 29, 2002, 1221 sites were listed on the final NPL, with 74 new sites proposed, 812 sites were reported to have completed construction, and 258 sites had been deleted from the list. The final NPL lists Superfund sites in which the clean-up plan is under construction or ongoing. NPL proposed sites include sites for which the HRS indicates that placement on the final NPL is appropriate. Among currently proposed NPL sites are Air Force Plant 85 near Columbus OH (**coal** deposits **leaching** sulfuric **acid**, ammonia, and **heavy metals**), Blackbird Mine in Lemhi ID (high levels of **arsenic**, **copper**, cobalt, and **nickel** in surface water and sediments of Meadow and Blackbird Creeks downstream from mining tunnels and waste-rock piles), the Omaha **Lead** site in Omaha, NE (lead **contaminated soil** near populated areas and **wetlands**) and the Libby **Asbestos** site in Libby, MT (heavy asbestos exposures and chromium, copper, and nickel deposits near wetlands and fisheries). A final NPL site is deleted from the list when it is determined that no further clean up is needed to protect human health or the environment Finally, under Superfund's redevelopment program, former hazardous-waste sites have been remade into office buildings, parking lots, or even **golf courses** to be re-integrated as productive parts of the community.

The offices and programs of the EPA recognize a set of main objectives, or "core functions." These core functions help define the agency's mission and provide a common focus for all agency activities. The core functions are:

- **Pollution** Prevention—taking measures to prevent pollution from being created rather than only cleaning up what has already been released, also known as source reduction
- Risk Assessment and Risk Reduction—identifying problems that pose the greatest risk to human health and the environment and taking measures to reduce those risks
- Science, Research and Technology—conducting research that will help in developing environmental policies and promoting innovative technologies to solve environmental problems
- Regulatory Development—developing requirements such as operating procedures for facilities and standards for emissions of pollutants
- Enforcement—assuring compliance with established regulations
- Environmental Education—developing educational materials, serving as an information clearinghouse, and providing grant assistance to local educational institutions

Many EPA programs are established by legislation enacted by Congress. For example, many of the activities carried out by the Office of Solid Waste and Emergency Response originated in the **Resource Conservation and Recovery Act** (RCRA). Among other laws that form the legal basis for the programs of the EPA are the National Environmental Policy Act (NEPA) of 1969, which represents the basic national charter of the EPA, the **Clean Air Act** (CAA) of 1970, the **Occupational Safety and Health Act** (OSHA) of 1970, the **Endangered Species Act** (ESA) of 1973, the **Safe Drinking Water Act** (SDWA) of 1974, the Toxic Substances Control Act (TSCA) of 1976, the **Clean Water Act** (CWA) of 1977, the Superfund Amendments and Reauthorization Act (SARA) of 1986, and the **Pollution Prevention Act** (PPA) of 1990. It is through such legislation that the EPA obtains authority to develop and enforce regulations. Environmental regulations drafted by

EPA organization chart. (Photograph by Tom Pantages. Reproduced by permission.)

the agency are subjected to intense review before being finalized. This process includes approval by the President's **Office of Management and Budget** and input from the private sector and from other government agencies.

Public concern over the environmental changes with time, and the EPA alters its policy priorities in response. For example, in answer to growing concern regarding environmental impact to children's health, the Office of Children's Health Protection (OCHP) was created in May 1997. On February 14, 2002, President George W. Bush announced the Clear Skies Initiative, which contain the farthest reaching legislative changes to the Clean Air Act since 1990.

Growing public concern about water pollution led to a landmark piece of legislation, the Federal Water **Pollution Control** Act of 1972, amended in 1977 and commonly known as the Clean Water Act. The Clean Water Act gives the EPA the authority to administer pollution control programs and to set **water quality standards** for contaminants of surface waters. October 18, 2002, marks the thirtieth Anniversary of the enactment of the Clean Water Act. In continuing support of the goals of this Act, Congress has proclaimed 2002 as the "Year of Clean Water."

As part of its mission as an information clearing house, the EPA maintains an excellent web site at <http://www.epa.gov> with countless links to supporting information of all kinds. The web site also includes Spanish translations of many documents, and links to children's activities.

Environmental racism

The term environmental racism was coined in a 1987 study conducted by the United Church of Christ that examined the location of **hazardous waste** dumps and found an "insidious form of racism." Concern had surfaced five years before, when opposition to a polychlorinated biphenyl (PCB) **landfill** prompted Congress to examine the location of hazardous waste sites in the Southeast, the **Environmental Protection Agency** (EPA)'s Region IV. They found that three of the four facilities in the area were in communities primarily inhabited by people of color. Subsequent studies, such as Ben Goldman's *The Truth about Where You Live*, have contended that exposure to environmental risks is significantly greater for racial and ethnic minorities than for nonminority populations. However, an EPA study contends that there is not enough data to draw such broad conclusions.

The *National Law Journal* found that official response to environmental problems may be racially biased. According to their study, penalties for environmental crimes were higher in white communities. They also found that the EPA takes 20% longer to place a hazardous waste site in a minority community on the Superfund's **National Priorities List** (NPL). And, once assigned to the NPL, these clean ups are more likely to be delayed.

Advocates also contend that environmentalists and regulators have tried to solve environmental problems without regard for the social impact of the solutions. For example, the Los Angeles Air Quality Management District wanted to require businesses to set up programs that would discourage their employees from driving to work. As initially conceived, employers could have simply charged fees for parking spaces without helping workers set up car pools. The Labor-Community Strategy Center, a local activist group, pointed out that this would have disproportionately affected people who could not afford to pay for parking spaces. As a compromise, regulators will now review employers' plans and only approve those that mitigate the any unequal effects on poor and minority populations.

In response to the concern that traditional **environmentalism** does not recognize the social and economic components of environmental problems and solutions, a national movement for "environmental and economic justice" has spread across the country. Groups like the Southwest Network for Environmental and Economic Justice attempt to frame the **environment** as part of the fight against racism and other inequalities.

In addition, the federal government has begun to address the debate over environmental racism. In 1992, the EPA established an Environmental Equity office. In addition, several bills that advocate environmental justice have been introduced. *See also* Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA); Environmental economics; Environmental law; Hazardous waste siting; South

Environmental refugees

The term environmental refugee was coined in the late 1980s by the **United Nations Environment Programme** and refers to people who are forced to leave their community of origin because the land can no longer support them. Environmental factors such as **soil erosion**, **drought**, or floods, which are often coupled with poor socioeconomic conditions, are the cause of this loss of **stability** and security. Many environmental influences may cause such a displacement and include the deterioration of agricultural land, natural or "unnatural" disasters, **climate** change, the destruction resulting from war, and environmental **scarcity**.

Environmental scarcity can be supply induced, demand induced, or structural. Supply induced scarcity refers to the depletion of agricultural resources, as in the erosion of cropland or **overgrazing**. Demand induced scarcity occurs when consumption of a resource increases or when **population growth** occurs, as is occurring in countries such as Philippines, Kenya, and Costa Rica. Structural scarcity results from the unequal social distribution of a resource within a community. The causes of environmental scarcity can occur simultaneously and in combination with each other, as seen in South Africa during the years of apartheid. Approximately 60% of the cropland in South Africa is marked by low organic content, and half of the country receives less than 19.5 in (500 mm) of annual precipitation. When these factors were

coupled with the rapid soil erosion, overcrowding, and unequal social distribution of resources experienced at this time, environmental scarcity resulted. Other environmental influences such as climate change and natural disasters can greatly compound the problems related to scarcity. Those countries which are especially vulnerable to these other influences are those which are already experiencing the precursors to scarcity, for example, highly populated countries such as Egypt and Bangladesh. On Haiti, per capita grain production is half of what it was only 40 years ago and residents only get about 80% of their minimum nutritional needs. Environmental problems place an added burden on a situation that is already under pressure. When this combination occurs in societies without strong social ties or political and economic stability, many times the people within the population have no choice but to relocate.

Environmental refugees tend to come from rural areas and developing countries--those most vulnerable to the influences of scarcity, climate change, and natural disasters. According to the **Centers for Disease Control and Prevention**, since the early 1960s most emergencies involving refugees have taken place in these **less developed countries** where resources are inadequate to support the population during times of need. In 1995, CDC directed 45 relief missions to developing countries such as Angola, Bosnia, Haiti, and Sierra Leone.

The number of displaced people is rising worldwide. Of these, the number forced to migrate because of economic and environmental conditions is growing more rapidly than refugees from political strife. According to Dr. Norman Myers at the University of Oxford, there are 25 million environmental refugees today, compared with 20 million officially recognized refugees migrating due to political, religious, or ethical problems. It has been predicted that by the year 2010, this number could rise to 50 million. The number of migrants seeking environmental refuge is grossly underestimated because many do not actually cross borders but are forced to wander within their own country. As global warming causes major climate changes, these numbers could increase even more. Climate change alone may displace 150 million more people by the middle of the next century. Not only would a global climate change increase the number of refugees, it could have a negative impact on agricultural production which would seriously limit the amount of food surpluses available to help displaced people.

Although approximately three out of every five refugees are fleeing from environmental hardships, this group of refugees is not legally recognized. According to the 1951 Convention on the Status of Refugees as modified by the 1967 Protocol, a legal refugee is a person who escapes a country and cannot re-enter due to fear of persecution for reasons of race, religion, nationality, social affiliation, or political opinion. This definition requires both the element of persecution as well as cross-border **migration**. Because of these two requirements, states are not legally compelled to recognize environmental refugees; as mentioned above, many of these refugees never leave their own country, and it is unreasonable to expect them to prove fear of persecution. Environmental refugees are often forced to enter a country illegally since they cannot be granted protection or asylum. Many of the Mexican immigrants who enter the United States are escaping the sterile, unproductive land they have been living on. Over 60% of the land in Mexico is degraded, with soil erosion contributing to over 494,000 acres (200,000 ha) more land being rendered unproductive every year. Many of the people considered to be economic migrants are actually environmental refugees. Those that are recognized as political refugees often must live in overcrowded refugee camps which are no more prepared to sustain the population than the land they are escaping from. Two thousand Somali refugees forced to live in such camps on the border of Kenya were displaced once more when **flooding** in 1994 ended a long drought but destroyed relief food. Many environmental refugees never resettle and must live the rest of their lives migrating from place to place, looking for land that can sustain them.

Researchers are currently working on ways to predict where the next large migrations will come from and how to prevent them from occurring. Predictive models are extremely difficult to produce because of the interaction between the socioeconomic status of the people and the environmental influences on the land. Stuart Liederman, an environmental scientist at the University of New Hampshire, is developing a model which will predict which areas are at risk of producing environmental refugees. This model is a mathematical formula which could be used with any population. One side of the equation combines the rate of environmental decay, the amount of time over which this deterioration will take place, and the susceptibility of the people and the **environment**. The other side of the equation combines the restoration rate, the time it would take to reestablish the environment, and the potential for recovery of the people and the land. These predictions will allow for preventive measures to be taken, for preparations to be made for future refugees, and for restoring the devastated homelands of past migrants. Creation of a working model may also help convince policymakers that those escaping unlivable environmental conditions need to be legally recognized as refugees.

Until environmental refugees are granted legal status, there will be no protection or compensation granted these individuals. The most effective way to deal with the growing number of displaced persons is to concentrate on the reasons they are being forced to leave their homelands. The increasing number of people forced to leave their homeland due

to ecological strife is an indicator of environmental quality. Environmental protection is necessary to prevent the situation in many countries from getting worse. In the meantime, measures must be taken to accommodate the needs of these refugees, and the environment must be recognized as a legitimate source of conflict for individuals seeking protection in other lands.

Environmental resources

An environmental resource is any material, service, or information from the **environment** that is valuable to society. This can refer to anything that people find useful in their environs, or surroundings. Food from plants and animals, wood for cooking, heating, and building, metals, **coal**, and oil are all environmental resources. Clean land, air, and water are environmental resources, as are the abilities of land, air, and water to absorb society's waste products. Heat from the sun, **transportation** and **recreation** in lakes, rivers, and oceans, a beautiful view, or the discovery of a new **species** are all environmental resources.

The environment provides a vast array of materials and services that people use to live. Often these resources have competing uses and values. A piece of land, for instance, could be used as a farm, a park, a parking lot, or a housing development. It could be mined or used as a **garbage** dump. The topic of environmental resources, then, raises the question, what do people find valuable in their environment, and how do people choose to use the resources that their environment provides?

Some resources are renewable, or infinite, and some are non-renewable, or finite. Renewable resources like energy from the sun are plentiful and will be available for a long time. Finite resources, like oil and coal, are non-renewable because once they are extracted from the earth and burned they cannot be used again. These resources are in limited supply and need to be used carefully. Many resources are becoming more and more limited, especially as population and industrial growth place increasing pressure on the environment. Before the Industrial Revolution, for example, people relied on their own strength and their animals for work and transportation. The invention of the steam engine in the 1850s radically altered peoples' ability to do work and to consume energy. Today we have transformed our environment with machines, cars, and **power plants** and in the process we have burnt extraordinary amounts of coal, oil, and **natural gas**. Some predict that world coal deposits will last another 200 years, while oil and natural gas reserves will last another one hundred years at current rates of consumption. This rate of use is clearly not sustainable. The terms finite and infinite are important because they indicate how much of a given resource is available, and how fast people can use that resource without limiting future supplies.

Some resources that were once taken for granted are now becoming more valuable. One of these resources is the environment's ability to absorb the waste that people produce. In Jakarta, Indonesia, people living in very close quarters in small shanties along numerous tidal canals use their only water supply for bathing, washing clothes, drinking water, fishing, and as a toilet. It is common to see people bathing just down stream from other people who are defecating directly into the river. This scene illustrates a central problem in environmental resource management. These people have only one water source and many needs in order to live. The demands that they place on these resources seriously affect the health and quality of life for all the people, but all of the needs must be met in some way. Thoughtful management of these environmental resources, like building latrines, could alleviate some of the strain on the river and improve other uses of the same resource. People all over the world have taken for granted the valuable resources of air, land, and **water quality** so that many rivers are undrinkable and unswimable because they contain raw sewage, chemical fertilizers, and industrial wastes. As people make decisions about what they will take from their environment, they also must be conscious of what they intend to put back into that environment.

Resource economics was established during a time in human history when environmental resources were thought to be limitless and without value until they were harvested

and brought to market. From this viewpoint, the world is big enough that when one resource is exhausted another resource can be found to take its place. Land is valuable according to what can be taken from it in order to make a profit. This kind of management leads to enormous short term gains and is responsible for the speed and efficiency of economic growth throughout the world. One the other hand, this view overlooks longer term profits and the reality that the world is an increasingly small, interconnected, and fragile system. People can no longer assume that they can find fresh new supplies when they use up what they have. Very few places on earth remain untouched and unexploited.

The world's remaining forests, if managed with care, could supply all of society's needs for timber and still remain relatively healthy and intact. Forest resources can be renewable, since forests grow quickly enough to replace themselves if used in moderation. Unfortunately, in many places forests are being destroyed at an alarming rate. In Costa Rica, Central America, 25% of the remaining forest land has disappeared since 1970. These forests have been cleared to harvest tropical hardwoods, to create farmland and pasture for animals, and to forage wood for cooking and heating. In a country struggling for economic growth, these are all important needs, but they do not always make long term economic sense. Farmers who graze cattle in tropical rain forests or who clear trees off of steep hillsides destroy their land in a matter of years with the idea that this is the fastest way to make money. In the same way, loggers harvest trees for immediate sale, even though many of these trees take hundreds of years to replenish themselves. In fact, the price for tropical hardwoods has gone up four-fold since 1970. The trees cut and sold in 1970 represent a huge economic loss to the Costa Rican economy, since they were sold for a fraction of their present value. Often, the **soil** on this land quickly erodes downhill into streams and rivers, clogging the rivers with **sediment** and killing fish and other **wildlife**. This has the added drawback of damaging hydroelectric and **irrigation dams** and hurting the fishing industry.

Despite these tragic losses, Costa Rica is a model in Central America and in the world for finding alternative uses for its **natural resources**. Costa Rica has set aside one fifth of its total land area for **nature** preserves and **national park** lands. These beautiful and varied parks are valuable for several reasons. First, they help to protect and preserve a huge diversity of tropical species, many undiscovered and unstudied. Second, they protect a great deal of vegetation that is important in producing oxygen, stabilizing atmospheric chemistry, and preventing global **climate** change. Third, the natural beauty of these parks attracts many international tourists. Tourism is one of Costa Rica's major industries, providing much needed economic development. People from around the world appreciate the beauty and the wonder—the intangible values—of these resources. Local people who would have been hired one time to cut down a forest can now be hired for a lifetime to work as park rangers and guides. Some would also argue that these nature preserves have value in themselves without reference to human needs, simply because they are filled with beautiful living birds, insects, plants, and animals.

Much of the dialogue in environmental resource management is about the need to balance the needs for economic growth and prosperity with needs for sustainable resource use. In a limited, finite world, there is a need to close the gap between the rates of consumption and rates of supply. The debate over how to assign value to different environmental resources is a lively one because the way that people think about their environment directly affects how they interact with the world.

Environmental science

Environmental science is often confused with other fields of related interest, especially **ecology**, environmental studies, **environmental education**, and **environmental engineering**. Renewed interest in environmental issues in the late 1960s and early 1970s, gave rise to numerous programs at many universities in the United States and other countries, most under two rubrics: environmental science or environmental studies. The former focused, as might be expected, on scientific questions and issues of environmental interest; the latter were often courses, with the emphasis on questions of **environmental ethics**, aesthetics, literature, etc.

These new academic units marked the first formal appearance of environmental science on most campuses, at least by that label. But environmental science is essentially the application of scientific methods and principles to the

study of environmental questions, so it has probably been around in some form as long as science itself. Air and **water quality** research, for example, have been carried on in many universities for many decades: that research is environmental science.

By whatever label and in whatever unit, environmental science is not constrained within any one discipline; it is a comprehensive field. A considerable amount of environmental research is accomplished in specific departments such as chemistry, physics, civil engineering, or the various biology disciplines. Much of this work is confined to a single field, with no interdisciplinary perspective. These programs graduate scientists who build on their specific training to continue work on environmental problems, sometimes in a specific department, sometimes in an interdisciplinary environmental science program.

Many new academic units are interdisciplinary, their members and graduates specifically designated as environmental scientists. Most have been trained in a specific discipline, but they may have degrees from almost any scientific background. In these units, the degrees granted—from B.S. to Ph.D.—are in Environmental Science, not in a specific discipline.

Environmental science is not ecology, though that discipline may be included. Ecologists are interested in the interactions between some kind of organism and its surroundings. Most ecological research and training does not focus on environmental problems except as those problems impact the organism of interest. Environmental scientists may or may not include organisms in their field of view: they mostly focus on the environmental problem, which may be purely physical in **nature**. For example, **acid deposition** can be studied as a problem of emissions and characteristics of the **atmosphere** without necessarily examining its impact on organisms. An alternate focus might be on the **acidification** of lakes and the resulting implications for resident fish. Both studies require expertise from more than one traditional discipline; they are studies in environmental science. *See also* Air quality; Environment; Environmental ethics; Nature; Water quality

Environmental stress

In the ecological context, environmental stress can be considered any environmental influence that causes a discernible ecological change, especially in terms of a constraint on **ecosystem** development. Stressing agents (or stressors) can be exogenous to the ecosystem, as in the cases of long-range transported acidifying substances, toxic gases, or pesticides. Stress can also cause change as a result of an accentuation of some pre-existing site factor beyond a threshold for biological tolerance, for example thermal **loading**, **nutrient** availability, wind, or temperature extremes.

Often implicit within the notion of environmental stress, particularly from the perspective of ecosystem managers, is a judgement about the quality of the ecological change. That is, from the human perspective, whether the effect is "good" or "bad."

Environmental stressors can be divided into several, not necessarily exclusive, classes of causal agencies:

- "Physical stress" refers to episodic events (or disturbance) associated with intense but usually brief loadings of kinetic energy, perhaps caused by a windstorm, volcanic eruption, tidal wave, or an explosion.
- Wildfire is another episodic stress, usually causing a mass **mortality** of ecosystem dominants such as trees or shrubs and a rapid **combustion** of much of the **biomass** of the ecosystem.
- Pollution occurs when certain **chemicals** are bio-available in a sufficiently large amount to cause toxicity. Toxic stressors include gaseous air pollutants such as **sulfur dioxide** and **ozone**, metals such as **lead** and **mercury**, residues of pesticides, and even nutrients that may be beneficial at small rates of supply but damaging at higher rates of loading.
- Nutrient impoverishment implies an inadequate availability of physiologically essential chemicals, which imposes an **oligotrophic** constraint upon ecosystem development.
- Thermal stress occurs when heat energy is released into an ecosystem, perhaps by aquatic discharges of low-grade heat from **power plants** and other industrial sources.
- Exploitative stress refers to the selective removal of particular **species** or size classes. Exploitation by humans includes the harvesting of forests or wild animals, but it can also involve natural herbivory and predation, as with infestations of defoliating insects such as locusts, spruce budworm, or **gypsy moth**, or irruptions of predators such as crown-of-thorns starfish.
- *Climatic stress* is associated with an insufficient or excessive regime of moisture, solar radiation, or temperature. These can act over the shorter term as weather, or over the longer term as **climate**.

Within most of these contexts, stress can be exerted either chronically or episodically. For example, the toxic gas sulfur dioxide can be present in a chronically elevated concentration in an urbanized region with a large number of point sources of **emission**. Alternatively, where the emission of sulfur dioxide is dominated by a single, large **point source** such as a **smelter** or power plant, the toxic stress associated with this gas occurs as relatively short-term events of **fumigation**.

Environmental stress can be caused by natural agencies as well as resulting directly or indirectly from the activities of humans. For example, sulfur dioxide can be emitted from smelters, power plants, and homes, but it can also be emitted in large quantities by volcanoes. Similarly, climate change has always occurred naturally, but it may also be forced by human activities that result in emissions of **carbon dioxide**, **methane**, and **nitrous oxide** into the **atmosphere**.

Over most of Earth's history, natural stressors have been the dominant constraints on ecological development. Increasingly, however, the direct and indirect consequences of human activities are becoming dominant environmental stressors. This is caused by both the increasing human population and by the progressively increasing intensification of the per-capita effect of humans on the **environment**.

Environmental Stress Index

Environmental Stress Index (ZPG) is a survey to determine the quality of life in American cities. Zero Population Growth, Inc. based in Washington D.C., conducted this "Urban Stress Test" in the late 1980s. One hundred and ninety-two cities were selected throughout the United States. The population-linked survey was based on 11 criteria: Population change; Population density; Education; Violent crime; Community economics; Individual economics (percent below federal poverty level and per capita income); Births (percent of teenage births and infant **mortality**); **Air quality** (meeting **Environmental Protection Agency** (EPA) standards); **Hazardous waste** (number of EPA-designated hazardous waste sites); Water (quality and supply); Sewage (model cities provide better than secondary treatment of their **wastewater**).

Cites were ranked one to six with number one being best. The cities with the lower scores were called model cities. The cities with the higher scores were called the stressed cities. Among the model cities were Abilene, Texas, with an index of 1.6; Roanoke, Virginia, 1.6; Berkeley, California, 2.0; Colorado Springs, Colorado, 2.0; and Peoria, Illinois, 2.0.

Among America's worst cities were Phoenix, Arizona, 5; Houston, Texas, 4.5; Los Angeles, 4.3; Honolulu, Hawaii, 4.3; and Baltimore, Maryland, 4.3.

Environmental Working Group

The Environmental Working Group is a public interest research group that monitors public agencies and public policies on topics relating to environmental and social justice. EWG publicizes its findings in research reports that emphasize both national and local implications of federal laws and activities. These research reports are based on analysis of public databases, often obtained through the Freedom of Information Act. In operation since 1993, EWG is a nonprofit organization funded by grants from private foundations. EWG is based in Washington, D.C. and Oakland, California, and is associated with the Tides Center of San Francisco. The organization performs its research both independently and in collaboration with other public interest research groups such as the **Sierra Club** and the Surface **Transportation** Policy Project (a nonprofit coalition focusing on social and environmental quality in transportation policy).

EWG specializes in analyzing large computer databases maintained by government agencies, such as the Toxic Release Inventory database maintained by the **Environmental Protection Agency** to record spills of toxic **chemicals** into the air or water, or the Regulatory Analysis Management System, maintained by the **Army Corps of Engineers** for internal tracking of permits granted for filling and draining **wetlands**. Because many of these data sources are capable of exposing actions or policies embarrassing to public agencies, EWG has often obtained data by using the Freedom of Information Act, which legally enforces public release of data belonging to the public domain. Many of the databases researched by EWG have never been thoroughly analyzed before, even by the agency collecting the data. EWG is unusual in working with primary data—going directly to the original database—rather than basing its research on secondary sources, anecdotal information, or interviews.

Research findings are published both in print and electronically on the Internet. Electronic publishing allows immediate and inexpensive distribution of reports that concern

issues of current interest. EWG is a prolific source of information, producing extensive, detailed reports, often at a rate of more than one a month. Among the environmental topics on which the EWG has reported are drinking **water quality**, wetland protection and destruction, and the impacts of agricultural pesticides on both farm workers and consumers. Social justice and policy issues that EWG has researched include campaign finance reform, inequalities and inefficiency in farm subsidy programs, and threats to public health and the **environment** from **medical waste**. For each general topic, EWG usually publishes a series of articles ranging from the nature and impacts of a federal law to what individuals can do about the current problem. Also included with research reports are state-by-state and county summaries of **statistics**, which provide details of local implications of the general policy issues.

Environmentalism

Environmentalism is the ethical and political perspective that places the health, harmony, and integrity of the natural **environment** at the center of human attention and concern. From this perspective human beings are viewed as *part of* **nature** rather than as overseers. Therefore to care for the environment is to care about human beings since we cannot live without the survival of the natural **habitat**.

Although there are many different views within the very broad and inclusive environmentalist perspective, several common features can be discerned. The first is environmentalism's emphasis on the interdependence of life and the conditions that make life possible. Human beings, like other animals, need clean air to breathe, clean water to drink, and nutritious food to eat. Without these necessities, life would be impossible. Environmentalism views these conditions as being both basic and interconnected. For example, fish contaminated with polychlorinated biphenyl (PCB), **mercury**, and other toxic substances are not only hazardous to humans but to bears, eagles, gulls, and other predators. Likewise, mighty **whales** depend on tiny **plankton**, cows on corn, koala bears on eucalyptus leaves, bees on flowers, and flowers on bees and birds, and so on through all **species** and ecosystems. All animals, human and nonhuman alike, are interdependent participants in the cycle of birth, life, death, decay, and rebirth.

A second emphasis of environmentalism is on the sanctity of life—not only human life but all life, from the tiniest microorganism to the largest whale. Since the fate of our species is inextricably tied with theirs and since life requires certain conditions to sustain it, environmentalists contend that we have an obligation to respect and care for the conditions that nurture and sustain life in its many forms.

While environmentalists agree on some issues, there are also a number of disagreements about the purposes of environmentalism and about how to best achieve those ends. Some environmentalists emphasize the desirability of conserving **natural resources** for **recreation**, sightseeing, **hunting**, and other human activities, both for present and **future generations**. Such a utilitarian view has been sharply criticized by Arne Naess and other proponents of **deep ecology** who claim that the natural environment has its own **intrinsic value** apart from any aesthetic, recreational, or other value assigned to it by human beings. Bears, for example, have their own intrinsic value or worth, quite apart from that assigned to their existence via **shadow pricing** or other mechanism by bear-watchers, hunters, or other human beings.

Environmentalists also differ on how best to conserve, reserve, and protect the natural environment. Some groups, such as the **Sierra Club** and **the Nature Conservancy**, favor gradual, low-key legislative and educational efforts to inform and influence policy makers and the general public about environmental issues. Other more radical environmental groups, such as the **Sea Shepherd Conservation Society** and **Earth First!**, favor carrying out direct action by employing the tactics of ecotage (ecological sabotage), or **monkey-wrenching**, to stop **strip mining**, **logging**, drift net fishing, and other activities that they deem dangerous to animals and ecosystems. Within this environmental spectrum are many other groups, including the **World Wildlife Fund**, **Greenpeace**, **Earth Island Institute**, Clean Water Action, and other organizations which use various techniques to inform, educate, and influence public opinion regarding environmental issues and to lobby policy makers.

Despite these and other differences over means and ends, environmentalists agree that the natural environment, whether valued instrumentally or intrinsically, is valuable and worth preserving for present and future generations.

Environmentally preferable purchasing

Environmentally preferable purchasing (EPP) invokes the practice of buying products with environmentally-sound qualities—reduced packaging, reusability, **energy efficiency**, recycled content and rebuilt or re-manufactured products. It was first addressed officially with Executive Order (EO) 12873 in October 1993, "Federal Acquisition, **Recycling** and Waste Prevention," but was further enhanced in September 14, 1998, in by EO 13101 also signed by President Clinton. Entitled, "Greening the Government through Waste Prevention, Recycling and Federal Acquisition," it superseded EO 12873, but retained similar directives for purchasing. The "Final Guidance" of directives was issued through the **Environmental Protection Agency** in 1995.

What the federal government would adopt as a guideline for its purchases also would mark the beginning of environmentally preferable purchasing for the private sector, and create an entirely new direction for individuals and businesses as well as governments. At the federal level, the EPA's "Final Guidance" was issued to apply to all acquisitions, from supplies and services to buildings and systems. It developed five "guiding principles" for incorporating the plan into the federal government setting.

The five guiding principles are listed as follows:

- Environment + Price + Performance = Environmentally Preferable Purchasing
- **Pollution** prevention
- Life cycle perspective/multiple attributes
- Comparison of environmental impacts
- Environmental performance information

Through its web site, in an entire section devoted to environmentally preferable purchasing, product and service information is provided that includes alternative fuels, buildings, cleaners, conferences, electronics, food serviceware, carpets, and copiers.

In the private world of business, environmentally preferable purchasing has promised to save money, in addition to meeting EPA regulations and improving employee safety and health. In an age of **environmental liability**, EPP can make the difference when a question of **environmental ethics**, or damage arises.

For the private consumer, purchasing "green" in the late 1960s and 1970s tended to mean something as simple as recycled paper used in Christmas cards, or unbleached natural fibers for clothing. By 2002, the average American home is affected in countless additional ways—energy efficient kitchen appliances and personal computers; environmentally-sound household cleaning products; and, neighborhood recycling centers. To be certified as "green" things such as recyclability, biodegradability, organic ingredients, and no **ozone** depleting **chemicals** are tested.

Of those everyday uses, the concern over cleaning products for home, industrial, and commercial use has been the focus of particular attention. Massachusetts has been one of the state's that has taken a lead in providing leadership on the issue of toxic chemicals with its **Massachusetts Toxic Use Reduction Act.** With a focus on products that have known carcinogens and ozone-depleting substances, excessive phosphate concentrations, and volatile organic compounds, testing has been continued to provide alternative products that are more environmentally acceptable—and safer for humans and all forms of life, as well. By 2002, the state had awarded contracts to six firms selling environmentally preferred cleaning agents.

The products approved for purchasing must follow the following mandated criteria:

- contain no ingredients from the Massachusetts Toxic Use Reduction Act list of chemicals
- contain no carcinogens appearing on lists established by the International Agency for Research on **Cancer**, the National Toxicology Program, or the **Occupational Safety and Health Administration**; and not contain any chemicals defined as Class A, B. or C carcinogens by the EPA
- contain no ozone-depleting ingredients
- must be compliant with the phosphate content levels stipulated in Massachusetts law
- must be compliant with the **Volatile Organic Compound** (VOC) content levels stipulated in Massachusetts law

The National Association of Counties offers an extensive list of EPP resources links through its web site. In addition to offices and agencies of the federal government, the states of Minnesota and Massachusetts, and the local governments of King County, Washington and Santa Monica, California, the list includes such organizations as, Buy Green, Earth Systems' Virtual Shopping Center for the En-

vironment (an online database of recycling industry products and services), the **Environmental Health** Coalition, **Green Seal**, the National Institute of Government Purchasing, Inc., and the National Pollution Prevention Roundtable. Businesses and business-related companies mentioned include the **Chlorine** Free Products Association, **Pesticide Action Network** of North America, Chlorine-Free Paper Consortium, and the Smart Office Resource Center.

Environmentally responsible investing

Environmentally responsible investing is one component of a larger phenomenon known as *socially responsible investing*. The idea is that investors should use their money to support industries whose operations accord with the investors' personal ethics. This concept is not a new one. In the early part of the century, Methodists, Presbyterians, and Baptists shunned companies that promoted sinful activities such as smoking, drinking, and gambling. More recently, many investors chose to protest apartheid by divesting from companies with operations in South Africa. Investors today might arrange their investment portfolios to reflect companies' commitment to affirmative action, human rights, **animal rights**, the **environment**, or any other issues the investors believe to be important.

The purpose of environmentally responsible investing is to encourage companies to improve their environmental records. The recent emergence and growth of mutual funds identifying themselves as environmentally oriented funds indicates that environmentally responsible investing is a popular investment area for the 1990s. In 1990, around $1 billion were invested in environmentally oriented mutual funds. The naming of these funds can be misleading, however. Some funds have been developed for the purpose of being environmentally responsible; others have been developed for the purpose of reaping the profits anticipated to occur in the environmental services sector as environmentalists in the marketplace and environmental regulations encourage the purchasing of **green products** and technology. These funds are not necessarily environmentally responsible; some companies in the environmental clean-up industry, for example, have less than perfect environmental records.

As the idea of environmentally responsible investing is still new, a generally accepted set of criteria for identifying environmentally responsible companies has not yet emerged. The fact is that everyone pollutes to some extent. The question is where to draw the line between acceptable and unacceptable behavior toward the environment.

When grading a company in terms of its behavior toward the environment, one could use an absolute standard. For example, one could exclude all companies that have violated any **Environmental Protection Agency** (EPA) standards. The problem with such a standard is that some companies that have very good overall environmental records have sometimes failed to meet certain EPA standards. Alternatively, a company could be graded on its efforts to solve environmental problems. Some investors prefer to divest of all companies in heavily polluting industries, such as oil and chemical companies; others might prefer to use a relative approach and examine the environmental records of companies within industry groups. By directly comparing oil companies with other oil companies, for example, one can identify the particular companies committed to improving the environment.

For consistency, some investors might choose to divest from all companies that supply or buy from an environmentally irresponsible company. It then becomes an arbitrary decision as to where this process stops. If taken to an extreme, the approach rejects holding United States treasury securities, since public funds are used to support the military, one of the world's largest polluters and a heavy user of nonrenewable energy.

A potential new indicator for identifying environmentally responsible companies has been developed by the Coalition for Environmentally Responsible Economies (CERES); it is a code called the **Valdez Principles**. The principles are the environmental equivalent of the Sullivan Principles, a

code of conduct for American companies operating in South Africa. The Valdez Principles commit companies to strive to achieve sustainable use of **natural resources** and the reduction and safe disposal of waste. By signing the principles, companies commit themselves to continually improving their behavior toward the environment over time. So far, however, few companies have signed the code, possibly because it requires companies to appoint environmentalists to their boards of directors.

As there is no generally accepted set of criteria for identifying environmentally responsible companies, investors interested in such an investment strategy must be careful about accepting "environmentally responsible" labels. Investors must determine their own set of screening criteria based on their own personal beliefs about what is appropriate behavior with respect to the environment.

Enzyme

Enzymes are catalysts, compounds (a protein) that speed up the rate at which chemical reactions occur within living organisms without undergoing any permanent change themselves. They are crucial to life since, without them, the vast majority of biochemical reactions would occur too slowly for organisms to survive.

In general, enzymes catalyze two quite different kinds of reactions. The first type of reaction includes those by which simple compounds are combined with each other to make new tissue from which plants and animals are made. For example, the most common enzyme in **nature** is probably carboxydismutase, the enzyme in green plants that couples **carbon dioxide** with an acceptor molecule in one step of the **photosynthesis** process by which carbohydrates are produced.

Enzymes also catalyze reactions by which more complex compounds are broken down to provide the energy needed by organisms. The principal digestive enzyme in the human mouth, for example, is ptyalin (also known as a -amylase), which begins the digestion of starch.

Enzymes have both beneficial and harmful effects in the **environment**. On the one hand, environmental hazards such as **heavy metals**, pesticides, and radiation often exert their effects on an organism by disabling one or more of its critical enzymes. As an example, **arsenic** is poisonous to animals because it forms a compound with the enzyme glutathione. The enzyme is disabled and prevented from carrying out its normal function, the maintenance of healthy red blood cells.

On the other hand, uses are now being found for enzymes in cleaning up the environment. For example, the Novo Nordisk company has discovered that adding an enzyme known as Pulpzyme® can vastly reduce the amount of **chlorine** needed to bleach wood pulp in the manufacture of paper. Since chlorine is a serious environmental contaminant, this technique may represent a significant improvement on present pulp and paper manufacturing techniques.

Ephemeral species

Ephemeral **species** are plants and animals whose lifespan lasts only a few weeks or months. The most common types of ephemeral species are **desert** annuals, plants whose seeds remain dormant for months or years but which quickly germinate, grow, and flower when rain does fall. In such cases the amount and frequency of rainfall determine entirely how frequently ephemerals appear and how long they last. Tiny, usually microscopic, insects and other invertebrate animals often appear with these desert annals, feeding on briefly available plants, quickly reproducing, and dying in a few weeks or less. Ephemeral ponds, short-duration desert rain pools, are especially noted for supporting ephemeral species. Here small insects and even amphibians have ephemeral lives. The spadefoot toad (*Scaphiopus multiplicatus*), for example, matures and breeds in as little as eight days after a rain, feeding on short-lived brine shrimp, which in turn consume algae and plants that live as long as water or **soil** moisture lasts. Eggs, or sometimes the larvae of these animals, then remain in the soil until the next moisture event.

Ephemerals play an important role in many plant communities. In some very dry deserts, as in North Africa, ephemeral annuals comprise the majority of living species—although this rich **flora** can remain hidden for years at a time. Often widespread and abundant after a rain, these plants provide an essential food source for desert animals, including domestic livestock. Because water is usually un-

available in such environments, many desert perennials also behave like ephemeral plants, lying dormant and looking dead for months or years but suddenly growing and setting seed after a rare rain fall.

The frequency of desert ephemeral recurrence depends upon moisture availability. In the Sonoran Desert of California and Arizona, annual precipitation allows ephemeral plants to reappear almost every year. In the drier deserts of Egypt, where rain may not fall for a decade or more, dormant seeds must survive for a much longer time before germination. In addition, seeds have highly sensitive germination triggers. Some annuals that require at least one inch (two to three cm) of precipitation in order to complete their life cycle will not germinate when only one centimeter has fallen. In such a case seed coatings may be sensitive to soil **salinity**, which decreases as more rainfall seeps into the ground. Annually-recurring ephemerals often respond to temperature, as well. In the Sonoran Desert some rain falls in both summer and winter. Completely different summer and winter floral communities appear in response. Such **adaptation** to different temporal niches probably helps decrease **competition** for space and moisture and increase each species' odds of success.

Although they are less conspicuous, ephemeral species also occur outside of desert environments. Short-duration food supplies or habitable conditions in some marine environments lead to ephemeral species growth. Ephemerals successfully exploit such unstable environments as volcanoes and steep slopes prone to slippage. More common are spring ephemerals in temperate deciduous forests. For a few weeks between snow melt and closure of the overstory canopy, quick-growing ground plants, including small lilies and violets, sprout and take advantage of available sunshine. Flowering and setting seed before they are shaded out by larger vegetation, these ephemerals disappear by mid-summer. Some persist in the form of underground root systems, but others are true ephemerals, with only seeds remaining until the next spring. *See also* Adaptation; Food chain/web; Opportunistic organism

Epidemiology

Epidemiology, the study of epidemics, is sometimes called the medical aspect of **ecology** because it is the study of diseases in animal populations, including humans. The epidemiologist is concerned with the interactions of organisms and their environments as related to the presence of disease. Environmental factors of disease include geographical features, **climate**, and concentration of pathogens in **soil** and water. Epidemiology determines the numbers of individuals affected by a disease, the environmental circumstances under which the disease may occur, the causative agents, and the transmission of disease.

Epidemiology is commonly thought to be limited to the study of infectious diseases, but that is only one aspect of the medical specialty. The epidemiology of the **environment** and lifestyles has been studied since Hippocrates's time. More recently, scientists have broadened the worldwide scope of epidemiology to studies of violence, of heart disease due to lifestyle choices, and to the spread of disease because of **environmental degradation**.

Epidemiologists at the Epidemic Intelligence Service (EIS) of the **Centers for Disease Control and Prevention** have played important roles in landmark epidemiologic investigations. Those include the identification in 1955 of a lot of poliovirus vaccine, supposedly dead, that was contaminated with live polio **virus**; an investigation of the definitive epidemic of Legionnaires' disease in 1976; identification of tampons as a risk factor for toxic-shock syndrome; and investigation of the first cluster of cases that came to be called acquired immunodeficiency syndrome (**AIDS**). EIS officers are increasingly involved in the investigation of noninfectious disease problems, including the risk of injury associated with all-terrain vehicles and cluster deaths related to flour contaminated with parathion.

The epidemiological classification of disease deals with the incidence, distribution, and control of disorders of a population. Using the example of typhoid, a disease spread through contaminated food and water, scientists first must establish that the disease observed is truly caused by *Salmonella typhosa*, the typhoid organism. Investigators then must know the number of cases, whether the cases were scattered over the course of a year or occurred within a short period, and the geographic distribution. It is critical that the precise locations of the diseased patients be established. In a hypothetical case, two widely separated locations within a city might be found to have clusters of cases of typhoid arising simultaneously. It might be found that each of these clusters revolved around a family unit, suggesting that personal rela-

tionships might be important. Further investigation might disclose that all of the infected persons had dined at one time or at short intervals in a specific home, and that the person who had prepared the meal had visited a rural area, suffered a mild attack of the disease, and now was spreading it to family and friends by unknowing contamination of food.

One very real epidemic of **cholera** in the West African nation of Guinea-Bissau was tracked by CDC researchers using maps, interviews, and old-fashioned footwork door-to-door through the country. An investigator eventually tracked the source of the cholera outbreak to contaminated shellfish.

Epidemic diseases result from an ecological imbalance of some kind. Ecological imbalance, and hence, epidemic disease may be either naturally caused or induced by man. A breakdown in **sanitation** in a city, for example, offers conditions favorable for an increase in the rodent population, with the possibility that diseases may be introduced into and spread among the human population. In this case, an epidemic would result as much from an alteration in the environment as from the presence of a causative agent. For example, an increase in the number of epidemics of viral encephalitis, a brain disease, in man has resulted from the ecological imbalance of mosquitoes and wild birds caused by man's exploitation of lowland for farming. Driven from their natural **habitat** of reeds and rushes, the wild birds, important natural hosts for the virus that causes the disease, are forced to feed near farms; mosquitoes transmit the virus from birds to cattle to man.

Lyme disease, which was tracked by epidemiologists from man to deer to the ticks which infest deer, is directly related to environmental changes. The lyme disease spirochete probably has been infecting ticks for a long time; museum specimens of ticks collected on Long Island in the 1940s were found to be infected. Since then, tick populations in the Northeast have increased dramatically, triggering the epidemic.

There are more ticks because many of the forests that had been felled in the Northeast have returned to forestland. Deer populations in those areas have exploded, close to concentrated human populations, as have the numbers of *Ixodes dammini* ticks which feed on deer. The deer do not become ill, but when a tick bite infects a human host, the result can be a devastating disease, including crippling arthritis and memory loss.

Disease detectives, as epidemiologists are called, are taking on new illnesses like heart disease and **cancer**, diseases that develop over a lifetime. In 1948, epidemiologists enrolled 5,000 people in Framingham, Massachusetts, for a study on heart disease. Every two years the subjects have undergone physicals and answered survey questions. Epidemiologists began to understand what factors put people at risk, such as high blood pressure, elevated cholesterol levels, smoking, and lack of exercise.

CDC epidemiologists are now tracking the pattern of violence, traditionally a matter for police. If a pattern is found, then young people who are at risk can be taught to stop arguments before they escalate to violence, or public health workers can recognize behaviors that lead to spouse abuse, or the warning signs of teenage suicide, for example.

In the 1980s, classic epidemiology discovered that a puzzling array of illnesses was linked, and it came to be known as AIDS. Epidemiologists traced the disease to sexual contact, then to contaminated blood supplies, then proved the AIDS virus could cross the placental barrier, infecting babies born to HIV-infected mothers.

The AIDS virus, called human immunodeficiency virus, may have existed for centuries in African monkeys and apes. Perhaps 40 years ago, this virus crossed from monkey to man, although researchers do not know how or why. African **chimpanzees** can be infected with HIV, but they don't develop the disease, suggesting that chimps have developed protective immunity. Eventually AIDS, over centuries, probably will develop into a less deadly disease in humans. But before then, researchers fear that new, more deadly, diseases will evolve.

As human communities change and create new ways for diseases to spread, viruses and bacteria constantly evolve as well. Rapidly increasing human populations prove a fertile breeding ground for **microbes**, and as the planet becomes more crowded, the distances that separate communities become smaller.

Epidemiology has become one of the important sciences in the study of nutritional and biotic diseases around the world. The United Nations supports, in part, a World Health Organization investigation of nutritional diseases.

Epidemiologists have also been called upon in times of natural emergencies. When **Mount St. Helens** erupted on May 18, 1980, CDC epidemiologists were asked to assist in an epidemiologic evaluation. The agency funded and assisted in a series of studies on the health effects of dust exposure, occupational exposure, and mental health effects of the volcanic eruption.

In 1990, CDC epidemiologists began research for the Department of Energy to study people who have been exposed to radiation. A major task of the study is to quantify exposures based on historical reconstructions of emissions from nuclear plant operations. Epidemiologists have undertaken a major thyroid disease study for those people exposed to radioactive iodine as a result of living near the **Hanford Nuclear Reservation** in Richland, Washington, during the 1940s and 1950s.

Erodible

Susceptible to **erosion** or the movement of **soil** or earth particles due to the primary forces of wind, moving water, ice and gravity. Tillage implements may also move soil particles, but this transport is usually not considered erosion.

Erosion

Erosion is the wearing away of the land surface by running water, wind, ice, or other geologic agents, including such processes as gravitational creep.

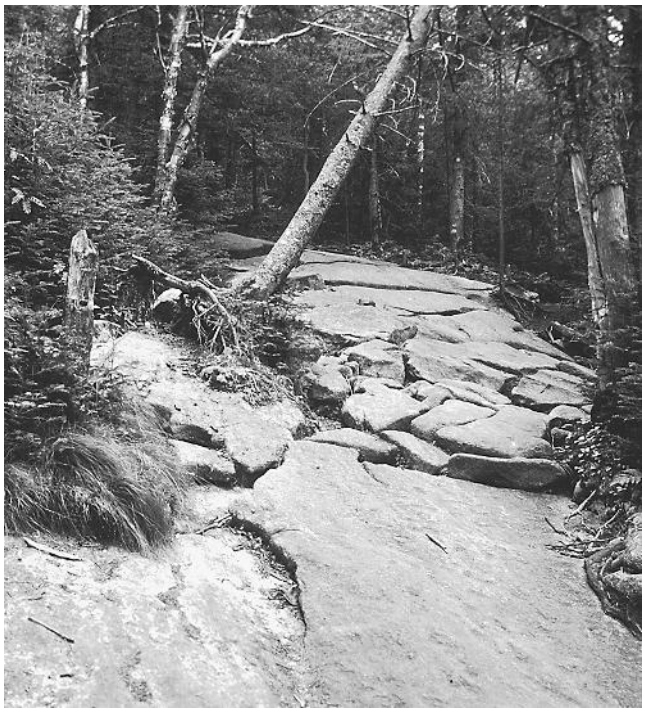
The term geologic erosion refers to the normal, natural erosion caused by geological processes acting over long periods of time, undisturbed by humans. Accelerated erosion is a more rapid erosion process influenced by human, or sometimes animal, activities. Accelerated erosion in North America has only been recorded for the past few centuries, and in research studies, postsettlement erosion rates were found to be eight to 350 times higher than presettlement erosion rates.

Soil erosion has been both accelerated and controlled by humans since recorded history. In Asia, the Pacific, Africa, and South America, complex **terracing** and other erosion control systems on **arable land** go back thousands of years. Soil erosion and the resultant decreased food supply have been linked to the decline of historic, particularly Mediterranean, civilizations, though the exact relationship with the decline of governments such as the Roman Empire is not clear.

A number of terms have been used to describe different types of erosion, including gully erosion, rill erosion, interrill erosion, sheet erosion, splash erosion, saltation, surface creep, suspension, and **siltation**. In gully erosion, water accumulates in narrow channels and, over short periods, removes the soil from this narrow area to considerable depths, ranging from 1.5 ft (0.5 m) to as much as 82–98 ft (25–30 m).

Rill erosion refers to a process in which numerous small channels of only a few inches in depth are formed, usually occurring on recently cultivated soils. Interrill erosion is the removal of a fairly uniform layer of soil on a multitude of relatively small areas by rainfall splash and film flow.

Usually interpreted to include rill and interril erosion, sheet erosion is the removal of soil from the land surface by rainfall and surface **runoff**. Splash erosion, the detachment and airborne movement of small soil particles, is caused by the impact of raindrops on the soil.



Saltation is the bouncing or jumping action of soil and mineral particles caused by wind, water, or gravity. Saltation occurs when soil particles 0.1–0.5 mm in diameter are blown to a height of less than 6 in (15 cm) above the soil surface for relatively short distances. The process includes gravel or stones effected by the energy of flowing water, as well as any soil or mineral particle movement downslope due to gravity.

Surface creep, which usually requires extended observation to be perceptible, is the rolling of dislodged particles 0.5–1.0 mm in diameter by wind along the soil surface. Suspension occurs when soil particles less than 0.1 mm diameter are blown through the air for relatively long distances, usually at a height of less than 6 in (15 cm) above the soil surface. In siltation, decreased water speed causes deposits water-borne sediments, or **silt**, to build up in stream channels, lakes, reservoirs, or flood plains.

In the water erosion process, the eroded **sediment** is often higher (enriched) in organic matter, **nitrogen**, **phosphorus**, and potassium than in the bulk soil from which it came. The amount of enrichment may be related to the soil, amount of erosion, the time of sampling within a storm, and other factors. Likewise, during a wind erosion event, the eroded particles are often higher in clay, organic matter, and plant nutrients. Frequently, in the Great Plains, the surface soil becomes increasingly more sandy over time as wind erosion continues.

Erosion estimates using the Universal Soil Loss Equation (USLE) and the Wind Erosion Equation (WEE) estimate erosion on a point basis expressed in mass per unit area. If aggregated for a large area (e.g., state or nation), very large numbers are generated and have been used to give misleading conclusions. The estimates of USLE and WEE indicate only the soil moved from a point. They do not indicate how far the sediment moved or where it was deposited. In cultivated fields, the sediment may be deposited in other parts of the field with different crop cover or in areas where the land slope is less. It may also be deposited in **riparian land** along stream channels or in flood plains.

Only a small fraction of the water-eroded sediment leaves the immediate area. For example, in a study of five river watersheds in Minnesota, it was estimated that from less than 1–27% of the eroded material entered stream channels, depending on the soil and topographic conditions. The deposition of wind-eroded sediment is not well quantified, but much of the sediment is probably deposited in nearby

Soil erosion on a trail in the Adirondack Mountains (Photograph by Yoav Levy. Phototake. Reproduced by permission.)

areas more protected from the wind by vegetative cover, stream valleys, road ditches, woodlands, or farmsteads.

While a number of national and regional erosion estimates for the United States have been made since the 1920s, the methodologies of estimation and interpretations have been different, making accurate time comparisons impossible. The most extensive surveys have been made since the Soil, Water and Related Resources Act was passed in 1977. In these surveys a large number of points were randomly selected, data assembled for the points, and the Universal Soil Loss Equation (USLE) or the Wind Erosion Equation (WEE) used to estimate erosion amounts. While these equations were the best available at the time, their results are only estimations, and subject to interpretation. Considerable research on improved methods of estimation is underway by the **U.S. Department of Agriculture**.

In the cornbelt of the United States, water erosion may cause a 1.7–7.8% drop in soil productivity over the next one hundred years, as compared to current levels, depending on the **topography** and soils of the area. The U.S.D.A. results, based on estimated erosion amounts for 1977, only included sheet erosion, not losses of plant nutrients. Though the figures may be low for this reason, other surveys have produced similar estimates.

In addition to depleting farmlands, eroded sediment causes off-site damages that, according to one study, may exceed on-site loss. The sediment may end up in a domestic water supply, clog stream channels, even degrade **wetlands**, **wildlife** habitats, and entire ecosystems. *See also* Environmental degradation; Gillied land; Soil eluviation; Soil organic matter; Soil texture

Escherichia coli

Escherichia coli, or *E. coli* is a bacterium in the family *Enterobacteriaceae* that is found in the intestines of warm-blooded animals, including humans. *E. coli* represent about 0.1% of the total bacteria of an adult's intestines (on a Western diet). As part of the normal **flora** of the human intestinal tract, *E. coli* aids in food digestion by producing vitamin K and B-complex vitamins from undigested materials in the large intestine and suppresses the growth of harmful bacterial **species**. However, *E. coli* has also been linked to diseases in about every part of the body. Pathogenic strains of *E. coli* have been shown to cause pneumonia, urinary tract infections, wound and blood infections, and meningitis.

Toxin-producing strains of *E. coli* can cause severe gastroenteritis (hemorrhagic colitis), which can include abdominal pain, vomiting, and bloody diarrhea. In most people, the vomiting and diarrhea stop within two to three days. However, about 5–10% of the those affected will develop hemolytic-uremic syndrome (HUS), which is a rare condition that affects mostly children under the age of 10, but also may affect the elderly as well as persons with other illnesses. About 75% of HUS cases in the United States are caused by an enterohemorrhagic (intestinally-related organism that causes hemorrhaging) strain of *E. coli* referred to as *E. coli* O157:H7, while the remaining cases are caused by non-O157 strains. *E. coli.* O157:H7 is found in the intestinal tract of cattle. In the United States, the **Centers for Disease**

Control and Prevention estimates that there are about 10,000–20,000 infections and 500 deaths annually that are caused by *E. coli* O157:H7.

E. coli O157:H7, first identified in 1982, and isolated with increasing frequency since then, is found in contaminated foods such as meat, dairy products, and juices. Symptoms of an *E. coli* O157:H7 infection start about seven days after infection with the bacteria. The first symptom is sudden onset of severe abdominal cramps. After a few hours, watery diarrhea begins, causing lose of fluids and electrolytes (dehydration), which causes the person to feel tired and ill. The watery diarrhea lasts for about a day, and then changes to bright red bloody stools, as the infection causes sores to form in the intestines. The bloody diarrhea lasts for two to five days, with as many as 10 bowel movements a day. Additional symptoms may include nausea and vomiting, without a fever, or with only a mild fever. After about five to 10 days, HUS can develop. HUS is characterized by destruction of red blood cells, damage to the lining of blood vessel walls, reduced urine production, and in severe cases, kidney failure. **Toxins** produced by the bacteria enter the blood stream, where they destroy red blood cells and platelets, which contribute to the clotting of blood. The damaged red blood cells and platelets clog tiny blood vessels in the kidneys, or cause lesions to form in the kidneys, making it difficult for the kidneys to remove wastes and extra fluid from the body, resulting in hypertension, fluid accumulation, and reduced production of urine. The diagnosis of an *E. coli* infection is made through a stool culture.

Treatment of HUS is supportive, with particular attention to management of fluids and electrolytes. Some studies have shown that the use of antibiotics and antimotility agents during an *E. coli* infection may worsen the course of the infection and should be avoided. Ninety percent of children with HUS who receive careful supportive care survive the initial acute stages of the condition, with most having no long-term effects. In about 50% of the cases, short term replacement of kidney function is required in the form of dialysis. However, between 10 and 30% of the survivors will have kidney damage that will lead to kidney failure immediately or within several years. These children with kidney failure require on-going dialysis to remove wastes and extra fluids from their bodies, or may require a kidney transplant.

The most common way an *E. coli* O157:H7 infection is contracted is through the consumption of undercooked ground beef (e.g., eating hamburgers that are still pink inside). Healthy cattle carry *E. coli* within their intestines. During the slaughtering process, the meat can become contaminated with the *E. coli* from the intestines. When contaminated beef is ground up, the *E. coli* bacteria are spread throughout the meat. Additional ways to contract an *E. coli* infection include drinking contaminated water and unpasteurized milk and juices, eating contaminated fruits and vegetables, and working with cattle. The infection is also easily transmitted from an infected person to others in settings such as day care centers and nursing homes when improper sanitary practices are used.

Prevention of HUS caused by ingestion of foods contaminated with *E. coli* O157:H7 and other toxin-producing bacteria is accomplished through practicing hygienic food preparation techniques, including adequate hand washing, cooking of meat thoroughly, defrosting meats safely, vigorous washing of fruits and vegetables, and handling leftovers properly. Irradiation of meat has been approved by the United States **Food and Drug Administration** and the United States Department of Agriculture in order to decrease bacterial contamination of consumer meat supplies.

The presence of *E. coli* in surface waters indicates that there has been fecal contamination of the water body from agricultural and/or urban and residential areas. However, the contribution from human vs. agricultural sources is difficult to determine. Since the concentration of *E. coli* in a surface water body is dependent on **runoff** from various sources of contamination, it is related to the **land use** and **hydrology** of the surrounding **watershed**. *E. coli* concentrations at a specific location in a water body will vary depending on the bacteria levels already in the water, inputs from various sources, dilution with precipitation and runoff, and **die-off** or multiplication of the organism within the water body. Sediments can act as a **reservoir** for *E. coli*, as the sediments protect the organisms from bacteriophages and microbial toxicants. The *E. coli* can persist in the sediments and contribute to concentrations in the overlying waters for months after the initial contamination.

Routine monitoring for enteropathogens, which cause gastrointestinal diseases and are a result of fecal contamination, is necessary to maintain water that is safe for drinking and swimming. Many of these organisms are hard to detect, so monitoring of an **indicator organism** is used to determine fecal contamination. To provide safe drinking water, the water is treated with **chlorine**, ultra-violet light, and/or **ozone**. Traditionally fecal **coliform bacteria** have been used as the indicator organisms for monitoring, but the test for these bacteria also detects thermotolerant non-fecal coliform bacteria.

Therefore, the U.S. **Environmental Protection Agency** (EPA) is recommending that *E. coli* as well as enterococci be used as indicators of fecal contamination of a water body instead of fecal coliform bacteria. The test for *E. coli* does not include non-fecal thermotolerant coliforms. An epidemiological study has shown that even though the strains of *E. coli* present in a water body may not be pathogenic, these organisms are the best predictor of swimming-associated gastrointestinal illness.

The U.S. EPA recreational **water quality** standard is based on a threshold concentration of *E. coli* above which the health risk from waterborne disease is unacceptably high. The recommended standard corresponds to approximately 8 gastrointestinal illnesses per 1000 swimmers. The standard is based on two criteria: 1) a geometric mean of 126 organisms per 100 ml, based on several samples collected during dry weather conditions, or 2) 235 organisms/100 ml sample for any single water sample. During 2002, the U.S. EPA finalized guidance on the use of *E. coli* as the basis for bacterial water quality criteria to protect recreational freshwater bodies.

Essential fish habitat

Essential Fish Habitat (EFH) is a federal provision to conserve and sustain the habitats that fish need to go through their life cycles. The United States Congress in 1996 added the EFH provision to the Magnuson Fishery **Conservation** and Management Act of 1976. Renamed the Magnuson-Stevens Conservation and Management Act in 1996, the act is the federal law that governs marine (sea) fishery management in the United States.

The amended act required that fishery management plans include designations and descriptions of essential fish habitats. The plan is a document describing the strategy to reach management goals in a fishery, an area where fish breed and people catch them. The Magnuson-Stevens Act covers plans for waters located within the United States' **exclusive economic zone**. The zone extends offshore from the coastland for three to 200 miles.

The designation of EFH was necessary because the continuing loss of aquatic **habitat** posed a major longterm threat to the viability of commercial and recreational fisheries, Congress said in 1996. Lawmakers defined EFH as "those waters and substrate necessary to the fish for spawning, breeding, feeding, or growth to maturity". Substrate consists of **sediment** and structures below the water.

The Magnuson-Stevens Act called for identification of EFH by eight regional fishery management councils and the Highly Migratory Species Division of the National Marine Fisheries Service (NMFS), an agency of the Commerce Department's **National Oceanic and Atmospheric Administration** (NOAA). Under the Magnuson-Stevens Act, NOAA manages more than 700 **species**. These species range from tiny reef fish to large tuna.

NOAA Fisheries and the councils are required by the act to minimize "to the extent practicable" the adverse effects of fishing on EFH. The act also directed the councils and NOAA to devise plans to conserve and enhance EFH. Those plans are included in the management plans. Also in the plan are "habitat areas of particular concern." These areas within an EFH include rare habitat or habitat that is ecologically important.

Furthermore, the act required federal agencies to work with NMFS when the agencies plan to authorize, finance, or carry out activities that could adversely affect EFH. This process called an EFH consultation is required if the agency plans an activity like **dredging** near an essential fishing habitat. While NMFS does not have veto power over the project, NOAA Fisheries will provide conservation recommendations.

The eight regional fishery management councils were established by the 1976 Magnuson Fishery and Conservation Management Act. That legislation also established the exclusive economic zone and staked the United States' claim to it. The 1976 act also addressed issues such as foreign fishing and how to connect the fishing community to the management process, according to an NOAA report. The councils manage living marine resources in their regions and address issues such as EFH.

The New England Fishery Management Council manages fisheries in federal waters off the coasts of Maine, New Hampshire, Massachusetts, Rhode Island, and Connecticut. New England fish species include Atlantic cod, Atlantic halibut, and white hake.

The Mid-Atlantic Fishery Management Council manages fisheries in federal waters off the mid-Atlantic coast. Council members represent the states of New York,

New Jersey, Pennsylvania, Delaware, Maryland, and Virginia. North Carolina is represented on this council and the South Atlantic Council. Fish species found within this region include ocean quahog, Atlantic mackerel, and butterfish.

The South Atlantic Fishery Management Council is responsible for the management of fisheries in the federal waters within a 200-mile area off the coasts of North Carolina, South Carolina, Georgia, and east Florida to Key West. Marine species in this area include cobia, golden crab, and Spanish mackerel.

The Gulf of Mexico Fishery Management Council draws its membership from the Gulf Coast states of Florida, Alabama, Mississippi, Louisiana, and Texas. Marine species in this area include shrimp, red drum, and stone crab.

The Caribbean Fishery Management Council manages fisheries in federal waters off the Commonwealth of Puerto Rico and the U.S. Virgin Islands. The management plan covers coral reefs and species including queen triggerfish and spiny lobster.

The North Pacific Fishery Management Council includes representatives from Alaska and Washington state. Species within this area include **salmon**, scallops, and king crab.

The Pacific Fishery Management Council draws its members from Washington, Oregon, and California. Species in this region include salmon, northern anchovy, and Pacific bonito.

The Western Pacific Fishery Management Council is concerned with the United States exclusive economic zone that surrounds Hawaii, American Samoa, Guam, the Northern Mariana Islands, and other U.S. possessions in the Pacific. Fishery management encompasses coral and species such as **swordfish** and striped marlin.

Estuary

Estuaries represent one of the most biologically productive aquatic ecosystems on Earth. An estuary is a coastal body of water where chemical and physical conditions modulate in an intermediate range between the freshwater rivers that feed into them and the salt water of the ocean beyond them. It is the point of mixture for these two very different aquatic ecosystems. The freshwater of the rivers mix with the salt water pushed by the incoming tides to provide a **brackish** water **habitat** ideally suited to a tremendous diversity of coastal marine life.

Estuaries are nursery grounds for the developing young of commercially important fish and shellfish. The young of any **species** are less tolerant of physical extremes in their **environment** than adults. Many species of marine life cannot tolerate the concentrations of salt in ocean water as they develop from egg to subadult, and by providing a mixture of fresh and salt water, estuaries give these larval life forms a more moderate environment in which to grow. Because of this, the adults often move directly into estuaries to spawn.

Estuaries are extremely rich in nutrients, and this is another reason for the great diversity of organisms in these ecosystems. The flow of freshwater and the periodic **flooding** of surrounding marshlands provides an influx of nutrients, as does the daily surges of tidal fluctuations. Constant physical movement in this environment keeps valuable **nutrient** resources available to all levels within the **food chain/web**.

Coastal estuaries also provide a major **filtration** system for waterborne pollutants. This natural **water treatment** facility helps maintain and protect **water quality**, and studies have shown that one acre of tidal estuary can be the equivalent of a $75,000 waste treatment plant. When its value for **recreation** and seafood production are included in this estimate, a single acre of estuary has been valued at $83,000. An acre of farmland in America's Corn Belt, for comparison, has a top value of $1,200 and an annual income through crop production of $600.

Throughout the ages man has settled near bodies of water and utilized the bounty they provide, and the economic value of estuaries, as well as the fact that they are a coastal habitat, has made them vulnerable to exploitation. **Chesapeake Bay** on the Atlantic coast is the largest estuary in the United States, draining six states and the District of Columbia. It is the largest producer of oysters in the country; it is the single largest producer of blue crabs in the world, and 90 percent of the striped bass found on the East Coast hatch there. It one of the most productive estuaries in the world, yet its productivity has declined in recent decades due to a huge increase in the number of people in the region. Between the 1940s and the 1990s, the population jumped

from about three and a half million to over 15 million, bringing with it an increase in **pollution** and **overfishing** of the bay. **Sewage treatment** plants contribute large amounts of **phosphates**, while agricultural, urban, and suburban discharges deposit **nitrates**, which in turn contribute to algal blooms and oxygen depletion. Pesticides and industrial toxics also contribute to the bay's problems. Since the early 1980s concerted efforts to clean up the Chesapeake Bay and restore its seafood productivity have been undertaken by state and federal agencies. Progress has been made but there is still much to be done, both to restore this vital **ecosystem** and to insure prolonged cooperation between government agencies, industry, and the general populace. *See also* Agricultural pollution; Aquatic chemistry; Commercial fishing; Dissolved oxygen; Nitrates and nitrites; Nitrogen cycle; Restoration ecology

Ethanol

Ethanol is an organic compound with the chemical formula C_2H_5OH. Its common names include ethyl alcohol and grain alcohol. The latter term reflects one method by which the compound can be produced: the distillation of corn, sugar cane, wheat and other grains. Ethanol is the primary component in many alcoholic drinks such as beer, wine, vodka, gin, and whiskey. Many scientists believe that ethanol can and should be more widely used in automotive fuels. When mixed in a one to nine ratio with **gasoline**, it is sold as **gasohol**. The reduced costs of producing gasohol have only recently made it a viable economic alternative to other automotive fuels. *See also* Alternative fuels

Ethnobotany

The field of ethnobotany is concerned with the relationship between indigenous cultures and plants. Plants play a major and complex role in the lives of **indigenous peoples**, providing nourishment, shelter, and medicine. Some plants have had such a major effect on traditional cultures that religious ceremonies and cultural beliefs were developed around their use. Ethnobotanists study and document these relationships.

The discovery of many plant-derived foods and medicines first used by indigenous cultures has changed the modern world. On the economic side, the field of ethnobotany determines the traditional uses of plants in order to find other potential applications for food, medicine, and industry. As an academic discipline, ethnobotany studies the interaction between peoples and plant life to learn more about human culture, history, and development. Ethnobotany draws upon many academic areas including anthropology, archeology, biology, **ecology**, chemistry, geography, history, medicine, religious studies, and sociology to help understand the complex interaction between traditional human cultures and the plants around them.

Early explorers who observed how native peoples used plants then carried those useful plants back to their own cultures might be considered the first ethnobotanists, although that is not a word they would have used to describe themselves. The plant discoveries these explorers made caused the expansion of trade between many parts of the globe. For example, civilizations were changed by the discovery and subsequent trade of sugar, tea, coffee, and spices including cinnamon and black pepper.

During his 1492 voyage to the Caribbean, Christopher Columbus discovered **tobacco** in Cuba and took it back with him to Europe, along with later discoveries of corn, cotton, and allspice. Other Europeans traveling to the Americas discovered tomatoes, potatoes, cocoa, bananas, pineapples and other useful plants and medicines. Latex **rubber** was discovered in South America when European explorers observed native peoples dipping their feet in the rubber compound before walking across hot coals.

The study of plants and their place in culture has existed for centuries. In India the *vedas*, which are long religious poems that have preserved ancient beliefs for thousands of years, contain descriptions of the use and value of certain plants. Descriptions of how certain plants can be used have been found in the ancient Egyptian scrolls. More than 500 years ago the Chinese made records of medicinal plants. In ancient Greece, Aristotle wrote about the uses of plants in early Greek culture, and theorized that each plant had a unique spirit. The Greek surgeon Dioscorides in A.D. 77 recorded the medicinal and folk use of nearly 600 plants in the Mediterranean region. During the Middle Ages, there existed many accounts of the folk and medicinal use of plants in Europe in books called herbals.

As the study of plants became more scientific, ethnobotany evolved as a field. One of the most important contributors to the field was Carl Linnaeus, a Swedish botanist who developed the system of naming organisms that is still used today. This system of binomial classification gives each

organism a Latin genus and **species** name. It was the first system that enabled scientists speaking different languages to organize and accurately record new plant discoveries. In addition to naming the 5,900 plants known to European botanists, Linnaeus sent students around the world looking for plants that could be useful to European civilization. This was an early form of economic botany, an offshoot of ethnobotany that is interested primarily in practical developments of new uses for plants. Pure ethnobotany is more sociology-based, and is primarily interested in the cultural relationship of plants to the indigenous peoples who use them.

In the nineteenth century, bioprospecting, (the active search for valuable plants in other cultures) multiplied as exploration expanded across the globe. The most famous ethnobotanist of the 1800s was Richard Spruce, an Englishman who spent 17 years in the Amazon living among the native people and observing and recording their use of plants. Observing a native treatment for fever, Spruce collected cinchona bark from which the drug quinine was developed. Quinine has saved the lives of millions of people infected with **malaria**. Spruce also documented the native use of hallucinogenic plants used in religious rituals and the accompanying belief systems associated with these hallucinogenic plants.

Many native cultures on all continents believed that certain psychoactive plants that caused visions or hallucinations gave them access to spiritual and healing powers. Spruce discovered that for some cultures, plants were central to the way human life and the world was perceived. Thus, the field of ethnobotany began expanding from the study of the uses of plants to how plants and cultures interacted on more sociological or philosophical/religious grounds.

An American botanist named John Harshberger first coined the term "ethnobotany" in 1895, and the field evolved into an academic discipline in the twentieth century. The University of New Mexico offered the first master's degree in ethnobotany. Their program concentrated on the ethnobotany of the Native Americans of the southwestern United States.

In the twentieth century one of the most famous ethnobotanists and plant explorers was Harvard professor Richard Evans Schultes. Inspired by the story of Richard Spruce, Schultes lived for 12 years with several indigenous tribes in South America while he observed and documented their use of plants as medicine, poison, and for religious purposes. He discovered many plants that have been investigated for pharmaceutical use. His work also provided further insight into the use of hallucinogenic plants by native peoples and the cultural significance of that practice.

Interest in ethnobotany increased substantially in the 1990s. One study showed that the number of papers in the field doubled in the first half of the 1990s, when compared to the last half of the 1980s. By the early 2000s, several universities around the world offered graduate programs in ethnobotany, and undergraduate programs were becoming more common. By the start of twenty-first century, ethnobotany was an accepted academic field. In addition, the pharmaceutical industry continued to research plants used by indigenous cultures in a quest for new or more effective drugs.

Many countries conduct ethnobotanical studies of their native cultures. A research survey showed that nearly 40% of ethnobotanical studies are being conducted in North America, but other countries including Brazil, Columbia, Germany, France, England, India, China, and Kenya, are also active in the field. For instance, ethnobotanists in China and India are recording traditional medicine systems that use native plants. Researchers are also studying traditional **sustainable agriculture** methods in Africa in the hope of applying them to new drought-management techniques.

Interest in the field of ethnobotany has increased as scientists have learned more about indigenous cultures. "Primitive" people were once viewed as backward and lacking in knowledge compared to the "civilized" world, but ethnobotanists and other scientists have shown that native peoples often have developed sophisticated knowledge about preparing and using plants for food and medicine.

The ways in which people and plants interact are broad and complex, and the modern field of ethnobotany, in its many areas of inquiry, reflects this complexity. Areas of interest to ethnobotanists include traditional peoples' knowledge and interaction with plant life, traditional agricultural practices, indigenous peoples' conception of the world around them and the role of plants in their religious belief systems and rituals, how plants are used to make products and art objects, the knowledge and use of plants for medicine (a sub-field called ethnopharmacology), and the historical relationship between plants and past peoples (a sub-field called paleoethnobotany).

At the beginning of the twenty-first century, ethnobotanists are fighting a war against time, because the world's native cultures and stores of plant life are disappearing at a rapid pace. Language researchers have estimated that the world lost over half of its spoken languages in the twentieth century, and of the languages that remain, only 20% were being taught to young children in the early 2000s. The loss of traditional languages indicates that indigenous cultures are disappearing quickly as well. Historically, up to 75% of all useful plant-derived compounds have been discovered through the observation of folk and traditional plant use. Ethnobotanists are concerned that modern people will lose a storehouse of valuable plant knowledge, as well as rare

cultural and historical information, as these indigenous cultures disappear.

Ethnobotanists, like many scientists, are concerned about environmental devastation from development pressure and slash-and-burn agriculture in less developed regions that are rich and diverse in plant life, such as the Amazon rainforest. Harvard biologist E. O. Wilson has estimated that the world is losing as many as 74 species per day. To put ethnobotanists' concerns about forest loss in perspective, a single square kilometer of rainforest may contain more plant species than an area in North America equaling size of Vermont. And, of all the plant species in the rainforest, fewer than 1% have been scientifically analyzed for potential uses. Considering that 25% of all prescription drugs in the United States contain active ingredients derived from plants, the continuing loss of the world's plant communities could be an incalculable loss.

In the face of disappearing indigenous peoples and the loss of botanically rich **habitat**, ethnobotanists must work quickly. Active areas in the field of ethnobotany in the early 2000s include the identification of new plant-derived foods, fibers and pharmaceuticals, investigation of traditional agricultural methods and vegetation management, using traditional technologies for **sustainable development**, and the deeper understanding of ecology and ways to preserve the **biodiversity** of ecosystems.

Eurasian milfoil

Eurasian milfoil (*Myriophyllum spicatum*) is a feathery-looking underwater plant that has become a major nuisance in waterways in the United States. Introduced into the country over 70 years ago as an ornamental tank plant by the aquarium industry, it has since spread to the East Coast from Vermont to Florida and grows as far west as Wisconsin and Texas. It is also found in California. It is particularly abundant in the **Chesapeake Bay**, the Potomac River, and in some Tennessee Valley reservoirs.

Eurasian milfoil is able to tolerate a wide range of **salinity** in water and grows well in inland fresh waters as well as in **brackish** coastal waters. The branched stems grow from 1–10 ft (0.3–3 m) in length and are upright when young, becoming horizontal as they get older. Although most of the plant is underwater, the tips of the stems often project out at the surface. Where the water is hard, the stems may get stiffened by calcification. The leaves are arranged in whorls of four around the branches with 12–16 pairs of leaflets per leaf. As with other milfoils, the red flowers of Eurasian milfoil are small and inconspicuous. As fragments of the plant break off, they disperse quickly through an area, with each fragment capable of putting out roots and developing into a new plant. Due to its extremely dense growth, Eurasian milfoil has become a nuisance that often impedes the passage of boats and vessels along navigable waterways. It can cause considerable damage to underwater equipment and lead to losses of time and money in the maintenance and operation of shipping lanes. It also interferes with recreational water uses such as fishing, swimming, and diving. In the **prairie** lakes of North Dakota, the woody seeds of this plant are eaten by some waterfowl such as ducks. However, this plant appears to have little **wildlife** value, although it may provide some cover to fishlife.

Aquatic weed control experts recommend that vessels that have passed through growths of Eurasian milfoil be examined and plant fragments removed. They also advocate the physical removal of plant growths from shorelines and other areas with a high potential for dispersal. Additionally, chemical agents are also often used to control the weed. Some of the commonly used herbicides include **2,4-D** and Diquat. These are usually diluted with water and applied at the rate of one to two gallons per acre. The application of herbicides to control aquatic weed growth is regulated by environmental agencies due to the potential of harm to nontarget organisms. Application times are restricted by season and duration of exposure and depend on the kind of **herbi-**

cide used, its mode of action, and its impacts on the other biota in the aquatic system. *See also* Aquatic chemistry; Commercial fishing

see **Green politics**

European Union

The European Union (EU) is a political and monetary organization of European nations. Its members as of 2002 were Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, Luxembourg, the Netherlands, Portugal, Spain, Sweden, and the United Kingdom. While member states retain their national governments, the EU promulgates transnational laws and treaties, has a unified agricultural policy, and has removed trade barriers between members. The EU uses a common currency, the euro. The EU represents about a quarter of the global economy, roughly equal to that of the United States.

The European Union developed gradually in the years after World War II. It began in 1957 as the European Economic Community, or EEC, which originally included France, West Germany, Italy, Belgium, the Netherlands, and Luxembourg. The EEC was superceded by the European Community, or EC, in 1967. The principal aim of the EC was to foster free trade among member countries, eliminating tariffs and customs barriers. The EC expanded its role in the 1970s and 1980s. As more states joined, the EC began to strengthen political cooperation among members, holding meetings to coordinate foreign policy and international law. By the mid-1980s, plans were underway to transform the EC into a single European market. This single market would have a central banking system, a transnational currency, and a unified foreign policy. These goals were articulated in the Single European Act of 1987, which also for the first time set out environmental protection as an important goal of European economic development. A treaty written in 1991, called the Maastricht Treaty or the Treaty on European Union, spelled out the future shape of the European Union. All the member states had ratified the treaty by November, 1993, when the European Union officially superceded the EC. The EU went on to launch a new currency, the euro, in 1999. In January 2002 the euro replaced existing EU member currencies.

The EU had incorporated **environmental policy** into its economic plans beginning in 1987. New members were required to conform to certain environmental standards. And the EU was able to make regional environmental policy, which often made more sense than national laws for problems like air and **water pollution** that extended across national borders. Environmental regulation in the EU was generally stricter than in the United States, though member states did not always comply with the law. The EU was often quicker than the United States on implementing environmental strategy, such as rules for computer and cell phone disposal. The EU approved the 1997 Kyoto Protocol, an international agreement to reduce the production of so-called **greenhouse gases** in order to arrest global warming. As details of the implementation of the plan were being worked out over the next five years, EU negotiators remained committed to curtailing European gas emissions even after it became clear that the United States would not sign the Kyoto treaty. Sweden took over the rotating presidency of the EU in 2002, and planned to make environmental policy a high priority. "The **environment** is more global than anything else except foreign policy," Sweden's environmental minister and EU spokesman told *Harper's Bazaar* (March 2001). With the EU representing 25% of the global economy, the organization's stance on environmental issues was always significant.

Eutectic

Refers to a type of solar heating system which makes use of phase changes in a chemical storage medium. At its melting point, any chemical compound must absorb a quantity of heat in order to change phase from solid to liquid, and at its boiling point, it must absorb an additional quantity of heat to change to a gas. Conversely, a compound *releases* a quantity of heat when condensing or freezing. Therefore, a chemical warmed by **solar energy** through a phase change releases far more energy when it cools than, for example, water heated from a cool liquid to a warm liquid state. For this reason, solar heating systems that employ phase-changing **chemicals** can store more energy in a compact space than a water-based system.

Eutrophication

see **Cultural eutrophication**

Evapotranspiration

Evapotranspiration is a key part of the **hydrologic cycle**. Some water evaporates directly from soils and water bodies, but much is returned to the **atmosphere** by **transpiration** (a word combining transport and evaporation) from plants via openings in the leaves called stomata. Within the same climates, forests and lakes yield about the same amount of water vapor. The amount of evapotranspiration is dependent on energy inputs of heat, wind, humidity, and the amount of stored **soil** water. In **climate** studies this term is used to indicate levels of surplus or deficit in water budgets. Aridity may be defined as an excess of potential evapotranspiration over actual precipitation, while in humid regions the amount of **runoff** correlates well with the surplus of precipitation over evapotranspiration.

Everglades

A swampy region in southern Florida, the Everglades are described as a vast, shallow sawgrass (*Cladium effusum*) marsh with tree islands, wet prairies, and aquatic sloughs, the Everglades historically covered most of southeastern Florida, prior to massive **drainage** and **reclamation** projects launched at the turn of the century. The glades constitute the southern end of the Kissimmee Lake Okeechobee Everglades system, which encompasses most of south and central Florida below Orlando. Originally, the Everglades covered an area approximately 40 mi (64 km) wide and 100 mi (161 km) long, or 2.5 million acres, but large segments have been isolated by canals and levees. Today, intensive agriculture in the north and rapid urban development in the east are among the Everglades' various land uses.

Two general **habitat** regions can be demarcated in the Everglades. The first includes three **water conservation** areas, basins created to preserve portions of the glades and provide multiple uses, such as water supply. This region is located in the northern Everglades and contains most of the intact natural marsh. The second is the southern habitat, which includes the Everglades **National Park** and the southern third of the three water **conservation** areas. The park has been designated a World Heritage Site of international ecological significance, and the Everglades as a whole are one of the outstanding freshwater ecosystems in the United States.

Topographically flat, elevations in the Everglades are generally less than 20 ft (6.1 m). The ground slopes north to south at an average gradient of 0.15 ft per mile, with the highest elevations in the north and the lowest in the south. The **climate** is generally subtropical, with long, hot, humid, and wet summers from May to October followed by mild, dry winters from November to April. During the wet season severe storms can result in lengthy periods of **flooding**, while during the dry season cool, sometimes freezing temperatures can be accompanied by thunderstorms, tornadoes, and heavy rainfall.

Before the Everglades were drained, large areas of the system were inundated each year as Lake Okeechobee overflowed its southern rim. The "River of Grass" flowed south and was in constant flux through **evapotranspiration**, rainfall, and water movement into and out of the Everglades' **aquifer**. The water discharged into the tidewaters of south Biscayne Bay, Florida Bay, and Ten Thousand Islands.

In the early 1880s, Philadelphia industrialist Hamilton Disston began draining the Everglades under a contract with Florida trustees. Disston, whose work ceased in 1889, built a substantial number of canals, mainly in the upper waters of the Kissimmee River, and constructed a canal between Lake Okeechobee and the Calooshatchee River to provide an outlet to the Gulf of Mexico. The Miami River was channelized beginning in 1903, and other canals—the Snapper Creek Canal, the Cutler Canal, and the Coral Gables Waterway—were opened to help drain the Everglades. Water tabless in south Florida fell 5–6 ft (1.5–1.8 m) below 1900 levels, causing stress to **wetlands** systems and losses of peat up to 6 ft (1.8 m) in depth.

Full-scale drainage and reclamation occurred under Governor W.S. Jennings (1901–1905) and Governor Napoleon Bonaparte Broward (1905–1909). In 1907, the Everglades Drainage District was created and built six major canals over 400 miles long before it suffered financial collapse in 1928. These canals enabled agriculture to flourish within

the region. In the late 1920s, when settlers realized better water control and flood protection were needed, low muck levees were built along Lake Okeechobee's southwest shore, eliminating the lake's overflow south to the Everglades. But hurricanes in 1926 and 1928 breached the levees, destroying property and killing 2,100 people. As a result, the Lake Okeechobee Flood Control District was established in 1929, and over the following fifteen years the United States **Army Corps of Engineers** constructed and enlarged flood control canals.

It was only in the mid-1950s, with the development and implementation of the Central and Southern Florida Project for Flood Control & Other Purposes (C&SF Project), that water control took priority over uncontrolled drainage of the Everglades. The project, completed by 1962, was to provide flood protection, water supply, and environmental benefits over a 16,000 square-mile (41,440 sq-km) area. It consists of 1,500 miles (2,415 km) of canals and levees, 125 major water control structures, 18 major pumping stations, 13 boat locks, and several hundred smaller structures. Interspersed throughout the Everglades is a series of habitats, each dominated by a few or in some cases a single plant **species**. Seasonal wetlands and upland pine forests, which once dominated the historic border of the system, have come under the heaviest pressure from urban and agricultural development. In the system's southern part, freshwater wetlands are superseded by muhly grass (*Muhlenbergia filipes*), prairies, upland pine and tropical hardwood forests, and mangrove forests that are influenced by the tides.

Attached algae, also known as periphyton, are an important component of the Everglades food web, providing both organic food matter and habitat for various grazing invertebrates and forage fish that are eaten by wading birds, reptiles, and sport fish. These algae include calcareous and filamentous algae (*Scytonema hoffmani*, *Schizothrix calcicola*) and diatoms (*Mastogloia smithii v. lacustris*).Sawgrass (*Cladium jamaicense*) constitutes one of the main plants occurring throughout the Everglades, being found in 65–70% of the remaining freshwater marsh. In the north, the sawgrass grows in deep **peat soils** and is both dense and tall, reaching up to 10 ft (3 m) in height. In the south, it grows in low-**nutrient** marl soils and is less dense and shorter, averaging 2.5–5 ft (0.75–1.5 m). Sawgrass is adapted to survive both flooding and burning. Stands of pure sawgrass as well as mixed communities are found in the Everglades. The mixed communities can include maidencane (*Panicum hemitomon*) arrowhead (*Sagittaria lancifolia*), water hyssop (*Bacopa caroliniana*), and spikerush (*Eleocharis cellulosa*).

Wet prairies, which together with aquatic sloughs provide habitat during the rainy season for a wide variety of aquatic invertebrates and forage fish, are another important habitat of the Everglades system. They are seasonally inundated wetland communities that require certain standing water for six to ten months. Once common, today more than 1,500 square miles (3,885 sq km) of these prairies have been drained or destroyed. The lowest elevations of the Everglades are ponds and sloughs, which have deeper water and longer inundation periods. They occur throughout the system, and in some cases can be formed by alligators in peat soils. Among the types of emergent vegetation commonly found in these areas are white water lily (*Nymphaea odorata*), floating heart (*Nymphoides aquatica*), and spatterdock (*Nuphar luteum*). Common submerged species include bladderwort (*Utricularia*) and the periphyton mat community. Ponds and sloughs serve as important feeding areas and habitat for Everglades **wildlife**.

At the highest elevations are found communities of isolated trees surrounded by marsh called tree islands. These provide nesting and roosting sites for colonial birds and habitat for deer and other terrestrial animals during high-water periods. Typical dominant species constituting tree islands are red bay (*Persa borbonia*), swamp bay (*Magnolia virginiana*), dahoon holly (*Ilex cassine*), pond apple (*Annona glabra*), and wax myrtle (*Myrica cerifera*). Beneath the canopy grows a dense shrub layer of cocoplum (*Chrysobalanus icacao*), buttonbush (*Cephalanthus accidentalis*), leather leaf fern (*Acrostichum danaeifolium*), royal fern (*Osmunda regalis*), cinnamon fern (*O. cinnamonea*), chain fern (*Anchistea virginica*), bracken fern (*Pteridium aquilinium*), and lizards tail (*Saururus cernuus*).

In addition to the indigenous plants of the Everglades, numerous exotic and nuisance species have been brought into Florida and have now spread in the wild. Some threaten to invade and displace indigenous species. Brazilian pepper (*Schinus terebinthifolius*), Australian pine (*Casuarina equisetifolia*), and melaleuca (*Melaleuca quinquenervia*) are three of the most serious **exotic species** that have gained a foothold and are displacing native plants.

The Florida Game and Fresh Water Fish Commission has identified 25 threatened or endangered species with the Everglades. Mammals include the **Florida panther** (*Felis concolor coryi*), mangrove fox squirrel (*Sciurus niger avicennia*), and black bear (*Ursus americanus floridanus*). Birds include the wood stork (*Mycteria americana*), snail kite (*Rostrhamus sociabilis*), and the red-cockaded (*Picoides borealis*). Endangered or threatened reptiles and amphibians include the gopher tortoise (*Gopherus polyphemus* the eastern indigo snake (*Drymarchon corais couperi*), and the loggerhead **sea turtle** (*Caretta caretta*).

The alligator (*Alligator mississippiensis*) was once endangered due to excessive alligator hide **hunting**. In 1972, the state made alligator product sales illegal. Protection allowed the species to recover, and it is now widely distributed in wetlands throughout the state. It is still listed as threatened

A swampy area in the Everglades. (Photograph by Gerald Davis. Phototake. Reproduced by permission.)

by the federal government, but in 1988 Florida instituted an annual alligator harvest.

Faced with pressures on Everglades habitats and the species within them, as well as the need for water management within the rapidly developing state, in 1987 the Florida legislature passed the Surface Water Improvement and Management Act (1987). The law requires the state's five water management districts to identify areas needing preservation or restoration. The Everglades Protection Area was identified as a priority for preservation and improvement planning. Within the state's protection plan, excess nutrients, in large part from agriculture, have been targeted as a major problem that causes natural periphyton to be replaced by species more tolerant of **pollution**. In turn, sawgrass and wet **prairie** communities are overrun by other species, impairing the Everglades' ability to serve as habitat and forage for higher **trophic level** species.

A federal lawsuit was filed against the South Florida Management District in 1988 for **phosphorus** pollution, and in 1989, President George Bush authorized the addition of more than 100,000 acres to the Everglades National Park. The law that authorized this addition was Public Law 101-229 or the Everglades National Park Protection and Expansion Act of 1989. Included in this legislation was the stipulation that the Army Corps of Engineers improve water flow to the Park. In 1994, the Everglades Forever Act was passed by the Florida State Legislature. The Act called for construction of experimental marshes called Stormwater Treatment Areas that were designed to remove phosphorus from water entering the Everglades. In 1997, six more Stormwater Treatment Areas were constructed and **phosphorus removal** was estimated to be as much as 50%, due in part to better management practices that were mandated by the Everglades Forever Act. In 2000, President Clinton authorized the spending of billions of federal dollars to restore the Everglades, while Florida Governor Jeb Bush agreed to a state commitment of 50% of the cost, in a bill called the Florida Investment Act. In 2001 and 2002, the state of Florida, under Governor Jeb Bush, and the federal government, under President George W. Bush, committed $7.8 billion dollars to implement the Comprehensive Everglades Restoration Plan (CERP).

Evolution

Evolution is an all-pervading concept in modern science applied to physical as well as biological processes. The phrase *theory of evolution*, however, is most commonly associated with organic evolution, the origin and evolution of the enormous diversity of life on this planet.

The idea of organic evolution arose from attempts to explain the immense diversity of living organisms and dates from the dawn of culture. Attempts to formulate a naturalistic explanation of the phenomena of evolution in one form or another had been proposed, and by the end of the eighteenth century a number of naturalists from Carolus Linnaeus to Jean-Baptiste Lamarck had questioned the prevailing doctrine of fixity of **species**. Lamarck came the closest to proposing a complete theory of evolution, but for several reasons his theory fell short and was not widely accepted.

Two English naturalists conceived the first truly complete theory of evolution. In a most remarkable coincidence, working quite independently, Charles Darwin and Alfred Russell Wallace arrived at essentially the same thesis, and their ideas were initially publicized jointly in 1858. However,

it is to Charles Darwin that the recognition of the founder of modern evolution is attributed. His continued efforts toward a detailed development of the evidence and the explication of a complete, convincing theory of organic evolution resulted in the publication in 1859 of his book *On the Origin of Species by Natural Selection*. With the publication of this volume, widely regarded as one of the most influential books ever written, regardless of subject matter, the science of biology would never be the same.

Darwin was the first evolutionist whose theories carried conviction to a majority of his contemporaries. He set forth a formidable mass of supporting evidence in the form of direct observations from **nature**, coupled with a comprehensive and convincing synthesis of current knowledge. Most significantly, he proposed a rational, plausible instrumentality for evolutionary change: natural selection.

The theory Darwin presented is remarkably simple and rational. In brief, the theoretical framework of evolution presented by Darwin contained three basic elements. First is the existence of variation in natural populations. In nature there are no individuals who are exactly alike, therefore natural populations always consist of members who all differ from one another to some degree. Many of these differences are heritable and are passed on from generation to generation. Second, some of these varieties are better adapted to their **environment** than others. Third, the reproductive potential of populations is unlimited. All populations have the capacity to overproduce, but populations in nature are limited by high **mortality**. Thus, if all offspring cannot survive each generation, the better-adapted members have a greater **probability** of surviving each generation than those less adapted.

Thomas Henry Huxley, when first presented with Darwin's views, was supposed to have exclaimed: "How extremely stupid not to have thought of that." This apocryphal statement expresses succinctly the immediate intelligibility of this momentous discovery.

Darwin's theory as presented was incomplete, as he was keenly aware, but the essential parts were adequate at the time to demonstrate that the material causes of evolution are possible and can be investigated scientifically.

One of the most critical difficulties with Darwin's theory was the inability to explain the source of hereditary variations observed in populations and, in particular, the source of hereditary innovations which, through the agency of natural selection, could eventually bring about the transformation of a species. The lack of existing knowledge of the mechanism of heredity in the mid-1800s precluded a scientifically sound solution to this problem.

The re-discovery in 1900 of Gregor Mendel's experiments demonstrating the underlying process of inheritance did not at first provide a solution to the problem facing Darwinian evolutionary theory. In fact, in one of the most extraordinary paradoxes in the history of science, during the first decades of Mendelian genetics, a temporary decline occurred in the support of Darwinian selectionism. This was primarily because of the direction and level of research as much as the lack of knowledge in further details of the underlying mechanisms of inheritance.

It was not until the publication of Theodosius Dobzhansky's *Genetics and the Origin of Species* (1937) that the modern synthetic theory of evolution began to take form, renewing confidence in selectionism and the Darwinian theory. In his book, Dobzhansky, for the first time, integrated the newly developed mathematical models of population genetics with the fats of chromosomal theory and **mutation** together with observations of variation in natural populations.

Dobzhansky also stimulated a series of books by several major evolutionists which provided the impetus and direction of research over the next decade, resulting in a reformulation of Darwin's theory. This became known as the *synthetic theory of evolution*. Synthetic is used here to indicate that there has been a convergence and synthesis of knowledge from many disciplines of biology and chemistry.

The birth of molecular genetics in 1950 and the enormous expansion of knowledge in this area have affected the further development and refinement of the synthetic theory markedly. But it has not altered the fundamental nature of the theory. Darwin's initial concept in this expanded, modernized form has taken on such stature as to be generally considered as the most encompassing theory in biology. To the majority of biologists, the synthetic theory of evolution is a grand theory that forms the core of modern biology. It also provides the theoretical foundation upon which most all other theories find support and comprehension. Or, as the distinguished evolutionary biologist Dobzhansky so succinctly put it: "Nothing in life makes sense except in the light of evolution."

If the three main elements of the Darwinian theory were to be restated in terms of the modern synthetic theory, they would be as follows. First, genetic systems governing heredity in each organism are composed of genes and chromosomes which are discrete but tightly interacting units of different levels of complexity. The genes, their organized associations in chromosomes, and whole sets of chromosomes, have a large degree of **stability** as units. But these units are shuffled and combined in various ways by sexual processes of reproduction in most organisms. The result of this process, called *recombination*, maintains a considerable amount of variation in any population in nature without introducing any new hereditary factors. Genetic experimentation, is, in fact, occurring all the time in natural populations. Each generation, as a result of recombination, is made

up of members who carry different hereditary combinations drawn from the common pool of the population. Each member generation in turn interacts within the same environmental matrix which, in effect, "tests" the fitness of these hereditary combinations. The sole source of hereditary innovation from within the population, other than recombination, would come from mutation affecting individual genes, chromosomes or sets of chromosomes, which are then fed into the process of recombination.

Second, populations of similar animals—members of the same species—usually interbreed among themselves making up a common pool of genes. The gene pools of established populations in nature tend to remain at equilibrium from generation to generation. An abundance of evidence has established the fact, as Darwin and others before him had observed, that populations have greater reproductive capacity than they can sustain in nature.

Third, change, over time, in the makeup of the **gene pool**, may occur by one of four known processes: mutation, fluctuation in gene frequencies—known as "sampling errors," or "genetic drift," which is generally effective only in small, isolated populations—introduction of genes from other populations, and differential reproduction.

The first three of these processes do not produce adaptive trends. These are essentially random in their effects, usually nonadaptive and only rarely and coincidentally produce **adaptation**. Of the four processes, differential reproduction results in adaptive trends. Differential reproduction describes the consistent production of more offspring, on an average, by individuals with certain genetic characteristics than those without those characteristics. This is the modern understanding of natural selection, with emphasis upon success in reproduction. The Darwinian and Neo-Darwinian concepts, on the other hand, placed greater emphasis upon "survival of the fittest" in terms of mortality and survival. Natural selection, in the Darwinian sense, was non-random and produced trends that were adaptive. Differential reproduction produces the same result. In what may appear to be a paradox, differential selection also acts in stabilizing the gene pool by reducing the reproductive success of those members whose hereditary variation result in non-adaptive traits.

As Darwin first recognized, the link between variability or constancy of the environment and evolutionary change or stability is provided by natural selection. The interaction between organisms and their environment will inevitably affect the genetic composition of each new generation. As a result of differential selection, the most fit individuals, in terms of reproductive capacity, contribute the largest proportion of genes or alleles to the next generation. The direction in which natural selection guides the population depends upon both the nature of environmental change or stability and the content of the gene pool of the population.

From the very beginning, evolutionists have recognized the significance of the environment/evolution linkage. This linkage always involves the interactions of a great many individuals both within populations of a single species (intraspecific) and among members of different species (interspecific linkage). These are inextricably linked with changes in the physical environment.

Dobzhansky estimated that the world may contain four to five million different kinds of organisms, each exploiting in various ways a large number of habitats. The complexity of ecosystems is based upon thousands of different ways of exploiting the same habitats in which each species is adapted to its specifically defined **niche** within the total **habitat**. The diversity of these population-environment interactions is responsible for the fact that natural selection can be conservative—(normalizing selection)—and can promote constancy in the gene pool. It directs continuous change (directional selection), or promotes diversification into new species (diversifying selection).

Recent trends in research have been of special significance in understanding the dynamics of these processes. They have greatly increased the body of information related to the ecological dimension of **population biology**. These studies have developed methods of analysis and sophisticated models which have made major advances in the study and understanding of the nature of the selective forces that direct evolutionary change. It is increasingly clear that a reciprocal imperative exists between ecological and environmental studies to further our understanding of the role of evolutionary and counterrevolutionary processes affecting stability in biological systems over time. The urgency of the need for an expanded synthesis of ecological and evolutionary studies is driven by the accelerating and expanding counterrevolutionary changes in the world environment resulting from human actions.

Evolutionary processes are tremendously more complex in detail than this brief outline suggests. This spare outline, however, should be sufficient to show that here is a mechanism, involving materials and processes known beyond doubt to occur in nature, capable of shaping and changing species in response to the continuously dynamic universe in which they exist.

Exclusive economic zone

The Exclusive Economic Zone (EEZ) is a 200-mile boundary off the coasts of a nation that provides the exclusive right to fish, mine, and otherwise utilize the **natural resources** located within the zone. After World War II, many nations became concerned about the intrusion of foreign fishing vessels into the rich and productive waters off of their coasts. The 1958 Convention on Fishing and Conservation of Living Resources of the High Seas, established rules that allowed a coastal nation impose terms on the uses of natural resources of their coastal oceans. This effort at regulation was unsuccessful, and the rules were never put in place. The policy that ultimately established exclusive economic zones around sovereign nations resulted from provisions of the Third United Nations Conference on the Law of the Sea, held in 1973. As a result of the actions taken in 1958, virtually all of the world's fisheries are controlled by one nation or another. However, the controlling nation must provide access to the resources that it cannot harvest, and is responsible for preventing **pollution** and depletion of the resources in the waters that it controls. In the United States, the Fishery Conservation and Management Act of 1976 established the fishery conservation zone out to 200 miles, however, it wasn't until 1983 that the EEZ was created by presidential proclamation.

Existence value

see **Debt for nature swap**

Exotic species

Exotic **species** are organisms that are introduced to a region or **ecosystem**, often unintentionally, through human **migration** or trade. Some exotic species are useful to man, such as horses, goats, pigs, and edible plants including wheat and oats. These are examples of species that were brought to the Americas intentionally by European colonists. Other exotic species that were introduced accidentally such as the **Mediterranean fruit fly** (*Ceratitis capitata*), Japanese beetle (*Popillia japonica*), **Africanized bees** (*Apis mellifera scutellata*)(sometimes called killer bees), and Norway rat (*Rattus norvegicus*) have become pests. Many exotic species, including most tropical fish, birds, and houseplants brought to colder climates, can survive only under continuous care. A few prove extremely adaptable and thrive in their new **environment**, sometime becoming invasive and out competing native species.

The federal government's Office of Technology Assessment has estimated that more than 2,000 plant species introduced from around the world currently live and thrive in the United States, and that 15 of these have caused more than $500 million worth of damage. Economic costs associated with exotic species include agricultural losses, damage to infrastructure, as when aquatic plants clog water intakes, and the costs of attempts to restore native species whose survival is endangered by **introduced species**.

Exotic species are most are most destructive when they adapt readily to their new environment and compete successfully with native species. Unfortunately there is no sure way to know which introduced species will become invasive. Often these plant and animals turn out to be better competitors because, unlike native species, they have no natural pests, **parasites**, diseases, or predators in their new home.

Purple loosestrife (*Lythrum salicaria*) is an example of a plant that is kept in check in its native **habitat**, but is invasive in North America. This showy wetland plant with tall purple flowers may have arrived accidentally or been intentionally imported to North America as a garden ornamental. In its native northern Europe, resident beetles feed on its roots and leaves, keeping the loosestrife in check, so that it only appears occasionally and temporarily in disturbed sites. When loosestrife arrived in North America, the beetles, along with other pests and diseases, were left behind. Loosestrife has proven to be extremely adaptable and has become an aggressive weed across much of the American East and Midwest, often taking over an entire wetland and choking out other plants, eliminating much of the wetland **biodiversity**.

In addition to the competitive advantage of having few predators, invasive exotic plants and animals may have ecological characteristics that make them especially competitive. They can be hardy, adaptable to diverse habitat conditions, and able to thrive on a variety of food sources. They may reproduce rapidly, generating large numbers of seeds or young that spread quickly. If they are aggressive colonizers adapted to living in marginal habitat, introduced species can drive resident natives from their established sites and food sources, especially around the disturbed environments of human settlement.

This competitiveness has been a problem, for example, with house sparrows (*Passer domesticus*). These birds were intentionally introduced from Europe to North America in 1850 to control insect pests. Their aggressive foraging and breeding habits often drive native sparrows, martins, and bluebirds from their nests, and today they are one of the most common birds in North America. Exotic plants can also become nuisance species when they crowd, shade, or out-propagate their native competitors. They can be extraor-

dinarily effective colonists, spreading quickly and eliminating **competition** as they become established.

The list of species introduced to the Americas from Europe, Asia, and Africa is immense, as is the list of species that have made the reverse trip from the Americas to Europe, Asia, and Africa. Some notable examples are **kudzu** (*Pueraria lobata*), the **zebra mussel** (*Dreissena polymorpha*), Africanized bees *Apis mellifera scutellata*), and **Eurasian milfoil** (*Myriophyllum spicatum*).

Kudzu is a cultivated legume in Japan. It was intentionally brought to the southern United States for ground cover and **erosion** control. Fast growing and tenacious, kudzu quickly overwhelms houses, tangles in electric lines, and chokes out native vegetation.

Africanized "killer" bees were accidentally released in Brazil by a beekeeper in 1957. These aggressive insects have no more venom than standard honey bees (also an Old World import), but they attack more quickly and in great numbers. Breeding with resident bees and sometimes traveling with cargo shipments, Africanized bees have spread north from Brazil at a rate of up to 200 miles (322 km) each year and now threaten to invade commercially valuable fruit orchards and domestic bee hives in Texas and California.

The zebra mussel, accidentally introduced to the **Great Lakes** around 1985 presumably in ballast water dumped by ships arriving from Europe, colonizes any hard surface, including docks, industrial water intake pipes, and the shells of native bivalves. Each female zebra mussel can produce 50,000 eggs a year. Growing in masses with up to 70,000 individuals per square foot, these mussels clog pipes, suffocate native clams, and destroy breeding grounds for other aquatic animals. They are also voracious feeders, competing with fish and native mollusks for **plankton** and microscopic plants. The economy and environment of the Great Lakes now pay the price of zebra mussel infestations. Area industries spend hundreds of millions of dollars annually unclogging pipes and equipment, and commercial fishermen complain of decreased catches.

Eurasian milfoil is a common aquarium plant that can propagate from seeds or cuttings. A tiny section of stem and leaves accidentally introduced into a lake by a boat or boat trailer can grow into a huge mat covering an entire lake. When these mats have consumed all available nutrients in the lake, they die and rot. The rotting process robs fish and other aquatic animals of oxygen, causing them to die.

Exotic species have brought ecological disasters to every continent, but some of the most extreme cases have occurred on isolated islands where resident species have lost their defensive strategies. For example, rats, cats, dogs, and mongooses introduced by eighteenth century sailors have devastated populations of ground-breeding birds on Pacific islands. Rare flowers in Hawaii suffer from grazing goats and rooting pigs, both of which were brought to the island for food, but have escaped and established wild populations. Grazing sheep threaten delicate plants on ecologically fragile North Atlantic islands, while rats, cats, and dogs endanger northern seabird breeding colonies. Rabbits introduced into **Australia** overran parts of the island and wiped out hundreds of acres of grassland.

Humans have always carried plants and animals as they migrated from one region to another with little regard to the effects of these introductions might have on their new habitat. Many introduced species seem benign, useful, or pleasing to have around, making it difficult to predict which imports will become nuisance species. When an exotic plant or animal threatens human livelihoods or economic activity, as do kudzu, zebra mussels, and "killer" bees, people begin to seek ways to control these invaders.

Control efforts include using pesticides and herbicides, and introducing natural predators and parasites from the home range of the exotic plant or animal. For example, beetles that naturally prey on purple loosestrife have been experimentally introduced in American loosestrife populations. This deliberate introduction requires a great deal of care, research, and monitoring, however, to ensure that an even worse problem does not result, as happened with the house sparrow. Such solutions, and the time and money to develop them, are usually elusive and politically controversial, so in many cases effective control methods remain unavailable.

In 1999, President Bill Clinton signed the Executive Order on Invasive Species. This order established the Invasive Species Council to coordinate the activities of federal agencies, such as the Aquatic Nuisance Species Task Force, the Federal Interagency Committee for the Management of Noxious and Exotic Weeds, and the Committee on Environment and **Natural Resources**. The Invasive Species Council is responsible for the development of a National Invasive Species Management Plan. This plan is intended to be updated very two years to provide guidance and recommendations about the identification of pathways by which invasive species are introduced, and measures that can be taken for their control.

Non-profit environmental organizations across the globe are leading the effort for control of exotic species. For example, **The Nature Conservancy** has established Landscape Conservation Networks to address issues of land conservation that include invasive species management. These networks bring in outside experts and land conservation partners to develop innovative and cost effective means of controlling exotic species. The Great Lakes information Network, managed by the Great Lakes Commission based in Ann Arbor, Michigan, provides online access about environmental issues, including exotics species, in the Great

Lakes region. The Florida Exotic **Pest** Plant Council, founded in 1984, provides funding to organizations that educate the public about the impacts of exotic invasive plants in the State of Florida.

Experimental Lakes Area

The Experimental Lakes Area (ELA) in northwestern Ontario is in a remote landscape characterized by Precambrian bedrock, northern mixed-species forests, and **oligotrophic** lakes, bodies of water deficient in plant nutrients. The Canadian Department of Fisheries and Oceans began developing a field-research facility at ELA in the 1960s, and the area has become the focus of a large number of investigations by D. W. Schindler and others into chemical and biological conditions in these lakes.

Of the limnological investigations conducted at ELA, the best known is a series of whole-lake experiments designed to investigate the ecological effects of perturbation by a variety of **environmental stress** factors, including eutrophication, **acidification**, metals, **radionuclides**, and **flooding** during the development of reservoirs.

The integrated, whole-lake projects at ELA were initially designed to study the causes and ecological consequences of eutrophication. In one long-term experiment, Lake 227 was fertilized with phosphate and nitrate. This experiment was designed to test whether **carbon** could limit algal growth during eutrophication, so none was added. Lake 227 responded with a large increase in **primary productivity** by drawing on the **atmosphere** for carbon, but it was not possible to determine which of the two added nutrients, phosphate or nitrate, had acted as the primary limiting factor.

Observations from experiments at other lakes in ELA, however, clearly indicated that phosphate is the primary limiting **nutrient** in these oligotrophic water bodies. Lake 304 was fertilized for two years with **phosphorus**, **nitrogen**, and carbon, and it became eutrophic. It recovered its oligotrophic condition again when the phosphorus fertilization was stopped, even though nitrogen and carbon fertilization were continued. Lake 226, an hourglass-shaped lake, was partitioned with a vinyl curtain into two basins, one of which was fertilized with carbon and nitrogen, and the other with phosphorus, carbon, and nitrogen. Only the latter treatment caused an **algal bloom**. Lake 302 received an injection of all three nutrients directly into its hypolimnion during the summer. Because the lake was thermally stratified at that time, the hypolimnetic nutrients were not available to fertilize plant growth in the epilimnetic euphotic zone, and no algal bloom resulted. Nitrogen additions to Lake 227 were reduced in 1975 and eliminated in 1990. The lake continued with high levels of productivity by fixing nitrogen from the atmosphere.

Research of this sort was instrumental in confirming conclusively the identification of phosphorus as the most generally limiting nutrient to eutrophication of freshwaters. This knowledge allowed the development of **waste management** systems which reduced eutrophication as an environmental problem by reducing the phosphorus concentration in **detergents**, removing phosphorus from sewage, and diverting sewage from lakes.

Another well known ELA project was important in gaining a deeper understanding of the ecological consequences of the acidification of lakes. Sulfuric **acid** was added to Lake 223, and its acidity was increased progressively, from an initial **pH** near 6.5 to pH 5.0–5.1 after six years. Sulfate and **hydrogen** ions were also added to the lake in increasing concentrations during this time. Other chemical changes were caused indirectly by acidification: manganese increased by 980%, zinc by 550%, and **aluminum** by 155%.

As the acidity of Lake 223 increased, the **phytoplankton** shifted from a community dominated by golden-brown algae to one dominated by chlorophytes and dinoflagellates. **Species** diversity declined somewhat, but productivity was not adversely affected. A mat of the green alga *Mougeotia* sp. developed near the shore after the pH dropped below 5.6. Because of reduced predation, the density of cladoceran **zooplankton** was larger by 66% at pH 5.4 than at pH 6.6, and copepods were 93% more abundant. The nocturnal zooplankton predator *Mysis relicta*, however, was an important **extinction**. The crayfish *Orconectes virilis* declined because of reproductive failure, inhibition of carapace hardening, and effects of a parasite. The most acid-sensitive fish was the fathead minnow (*Pimephales promelas*), which declined precipitously when the lake pH reached 5.6.

The first of many year-class failures of lake trout (*Salvelinus namaycush*) occurred at pH 5.4, and failure of white sucker (*Catastomus commersoni*) occurred at pH 5.1. One minnow, the pearl dace (*Semotilus margarita*), increased markedly in abundance but then declined when pH reached 5.1. Adult lake trout and white sucker were still abundant, though emaciated, at pH 5.0–5.5, but in the absence of

successful reproduction they would have become extinct. Overall, the Lake 223 experiment indicated a general sensitivity of many organisms to the acidification of lake water. However, within the limits of physiological tolerance, the tests showed that there can be a replacement of acid-sensitive species by relatively tolerant ones.

In a similarly designed experiment in Lake 302, nitric acid was shown to be nearly as effective as sulfuric acid in acidifying lakes, thereby alerting the international community to the need to control atmospheric emissions of gaseous nitrogen compounds. *See also* Acid rain; Algicide; Aquatic chemistry; C:N ratio; Cultural eutrophication; Water pollution

Exponential growth

The distinction between arithmetic and exponential growth is crucial to an understanding of the nature of growth. Arithmetic growth takes place when a constant amount is being added, as when a child puts a dollar a week in a piggy-bank. Although the total amount increases, the amount being added remains the same. Exponential growth, on the other hand, is characterized by a constant or even accelerating rate of growth.

At a constant rate of increase, measured in percentages, the amounts added grow themselves. Growth is then usually measured in doubling times because these remain constant while the amounts added increase. When the annual rate of increase is 1%, the doubling time will be 70 years. From this fact, a simple formula to calculate doubling times given a rate of increase can be derived: dividing 70 by the percentage rate will yield the number of years it takes to double the original amount.

A savings account with, say, a fixed annual interest rate of 5% furnishes a convenient example. If the original deposit is $1,000, then the growth over the first year is $50. Over the second year, growth will be $52.50. In 14 years, there will be $2,000 in the account (70 divided by 5 equals 14). In the first period of 14 years, then, total growth will be $1,000, but in the second period of 14 years total growth will be $2,000, and so on. During the tenth 14-year period, $512,000 is added, and at the end of that period the total amount in the account will be $1,024,000. As this example illustrates, growth will be relatively slow initially, but it will start speeding up dramatically over time. When growth takes place at an accelerating rate of increase, doubling times of course will become shorter and shorter.

The notion of exponential growth is of particular interest in **population biology** because all populations of organisms have the capacity to undergo exponential growth. The biotic potential or maximum rate of reproduction for all living organisms is very high, that is to say that all **species** theoretically have the capacity to reproduce themselves many, many times over during their lifetimes. In actuality, only a few of the offspring of most species survive, due to reproductive failure, limited availability of space and food, diseases, predation, and other mishaps. A few species, such as the lemming, go through cycles of exponential **population growth** resulting in severe overpopulation. A catastrophic **dieback** follows, during which the population is reduced enormously, readying it for the next cycle of growth and dieback. Interacting species will experience related fluctuations in population levels. By and large, however, populations are held stable by environmental **resistance**, unless an environmental disturbance takes place.

Climatological changes and other natural phenomena may cause such **habitat** disturbances, but more usually they result from human activity. **Pollution**, **predator control**, and the introduction of foreign species into habitats that lack competitor or predator species are a few examples among many of human activities that may cause declines in some populations and exponential growth in others.

An altogether different case of exponential population growth is that of humans themselves. The human population has grown at an accelerating rate, starting at a low average rate of 0.002% per year early in its history and reaching a record level of 2.06% in 1970. Since then the rate of increase has dropped below 2%, but human population growth is still alarming and many scientists predict that humans are headed for a catastrophic dieback.

External costs

see **Internalizing costs**

Externality

Most economists argue that markets ordinarily are the superior means for fulfilling human wants. In a market, deals are ideally struck between consenting adults only when the parties feel they are likely to benefit. Society as a whole is thought to gain from the aggregation of individual deals that take place. The wealth of a society grows by means of what is called the hidden hand of free market mechanisms, which offers spontaneous coordination with a minimum of coercion and explicit central direction. However, the market system is complicated by so-called externalities, which are effects of private market activity not captured in the price system.

Economics distinguishes between positive and negative externalities. A positive externality exists when producers cannot appropriate all the benefits of their activities. An example would be research and development, which yields benefits to society that the producer cannot capture, such as employment in subsidiary industries. **Environmental degradation**, on the other hand, is a negative externality, or an imposition on society as a whole of costs arising from specific market activities. Historically, the United States have encouraged individuals and corporate entities to make use of **natural resources** on public lands, such as water, timber, and even the land itself, in order to speed development of the country. Many undesirable by-products of the manufacturing process, in the form of exhaust gases or toxic waste, for instance, were simply released into the **environment** at no cost to the manufacturer. The **agricultural revolution** brought new farming techniques that relied heavily on fertilizers, pesticides, and **irrigation**, all of which affect the environment. **Automobile** owners did not pay for the **air pollution** caused by their cars. Virtually all human activity has associated externalities in the environmental arena, which do not necessarily present themselves as costs to participants in these activities. Over time, however, the consequences have become unmistakable in the form of a serious depletion of renewable resources and in **pollution** of the air, water, and **soil**. All citizens suffer from such environmental degradation, though not all have benefited to the same degree from the activities that caused them.

In economic analysis, externalities are closely associated with common property and the notion of **free riders**. Many natural resources have no discrete owner and are therefore particularly vulnerable to abuse. The phenomenon of degradation of common property is known as the **Tragedy of the Commons**. The costs to society are understood as costs to nonconsenting third parties, whose interests in the environment have been violated by a particular market activity. The consenting parties inflict damage without compensating third parties because without clear property rights there is no entity that stands up for the rights of a violated environment and its collective owners.

Nature's owners are a collectivity which is hard to organize. They are a large and diverse group that cannot easily pursue remedies in the legal system. In attempting to gain compensation for damage and force polluters to pay for their actions in the future the collectivity suffers from the free rider problem. Although everyone has a stake in ensuring, for example, good **air quality**, individuals will tend to leave it to others to incur the cost of pursuing legal redress. It is not sufficiently in the interest of most members of the group to sue because each has only a small amount to gain. Thus, government intervention is called for to protect the interests of the collectivity, which otherwise would be harmed.

The government has several options in dealing with externalities such as pollution. It may opt for regulation and set standards of what are considered acceptable levels of pollution. It may require reduced **lead** levels in **gasoline** and require automakers to manufacture cars with greater fuel economy and reduced emissions, for instance. If manufacturers or social entities such as cities exceed the standards set for them, they will be penalized. With this approach, many polluters have a direct incentive to limit their most harmful activities and develop less environmentally costly technologies. So far, this system has not proved to be very effective. In practice, it has been difficult (or not politically expedient) to enforce the standards and to collect the fines. Supreme Court decisions since the early 1980s have reinterpreted some of the laws to make standards much less stringent. Many companies have found it cheaper to pay the fines than to invest in reducing pollution. Or they evade fines by declaring bankruptcy and reorganizing as a new company.

Economists tend to favor pollution taxes and **discharge** fees. Since external costs do not enter the calculations a producer makes, the producer manufactures more of the good than is socially beneficial. When polluters have to absorb the costs themselves, to internalize them, they have an incentive to reduce production to acceptable levels or to develop alternative technologies. A relatively new idea has been to give out marketable pollution permits. Under this system, the government sets the maximum levels of pollution it will tolerate and leaves it to the market system to decide who will use the permits. The costs of past pollution (in the form of permanent environmental damage or costly cleanups) will still be borne disproportionately by society as a whole. The government generally tries to make responsible

parties pay for clean-ups, but in many cases it is impossible to determine who the culprit was and in others the parties responsible for the pollution no longer exist.

A special case is posed by externalities that make themselves felt across national boundaries, as is the case with **acid rain**, **ozone layer depletion**, and the pollution of rivers that run through more than one country. Countries that suffer from environmental degradation caused in other countries receive none of the benefits and often do not have the leverage to modify the polluting behavior. International **conservation** efforts must rely on agreements specific countries may or may not follow and on the mediation of the United Nations. *See also* Internalizing cost; Trade in pollution permits

Extinction

Extinction is the complete disappearance of a **species**, when all of its members have died or been killed. As a part of natural selection, the extinction of species has been ongoing throughout the earth's history. However, with modern human strains on the **environment**, plants, animals, and invertebrates are becoming extinct at an unprecedented rate of thousands of species per year, especially in tropical rain forests. Many thousands more are threatened and endangered.

Scientists have determined that mass extinctions have occurred periodically in prehistory, coming about every 50 million years or so. The greatest of these came at the end of the Permian period, some 250 million years ago, when up to 96% of all species on the earth may have died off. Dinosaurs and many ocean species disappeared during a well-documented **mass extinction** at the end of the Cretaceous period (about 65 million years ago). It is estimated that of the billions of species that have lived on the earth during the last 3.5 billion years, 99.9% are now extinct.

It is thought that most prehistoric extinctions occurred because of climatological changes, loss of food sources, destruction of **habitat**, massive volcanic eruptions, or asteroids or meteors striking the earth. Extinctions, however, have never been as rapid and massive as they have been in the modern era. During the last two centuries, more than 75 species of mammals and over 50 species of birds have been lost, along with countless other species that had not yet been identified. James Fisher has estimated that since 1600, including species and subspecies, the world has lost at least 100 types of mammals and 258 kinds of birds.

The first extinction in recorded history was the European lion, which disappeared around A.D. 80. In 1534, seamen first began slaughtering the great auk, a large, flightless bird once found on rocky North Atlantic islands, for food and oil. The last two known auks were killed in 1844 by an Icelandic fisherman motivated by rewards offered by scientists and museum collectors for specimens. Humans have also caused the extinction of many species of marine mammals. Steller's sea cow, once found on the Aleutian Islands off Alaska, disappeared by 1768. The sea mink, once abundant along the coast and islands of Maine, was hunted for its fur until about 1880, when none could be found. The Caribbean monk seal, hunted by sailors and fishermen, has not been found since 1962.

The early European settlers of America succeeded in wiping out several species, including the Carolina parakeet and the **passenger pigeon**. The pigeon was one of most plentiful birds in the world's history, and accounts from the early 1800s describe flocks of the birds blackening the sky for days at a time as they passed overhead. By the 1860s and 1870s tens of millions of them were being killed every year. As a result of this **overhunting**, the last passenger pigeon, Martha, died in the Cincinnati Zoo in 1914. The pioneers who settled the West were equally destructive, causing the disappearance of 16 separate types of **grizzly bear**, six of **wolves**, one type of fox, and one cougar. Since the Pilgrims arrived in North America in 1620, over 500 types of native American animals and plants have disappeared.

In the last decade of the twentieth century, the rate of species loss was unprecedented and accelerating. Up to 50 million species could be extinct by 2050, with a rate of three per day. Most of these species extinctions will occur—and are occurring—in tropical rain forests, the richest biological areas on the earth. Rain forests are being cut down at a rate of one to two acres per second.

In 1988, Harvard professor and biologist **Edward O. Wilson** estimated the current annual rate of extinction at up to 17,500 species, including many unknown **rain forest** plants and animals that have never been studied or even seen, by humans. Botanist Peter Raven, director of the Missouri **Botanical Garden**, calculated that a total of one-quarter the world's species could be gone by 2010. A study by the **World Resources Institute** pointed out that humans have accelerated the extinction rate to 100 to 1,000 times its natural level.

While it is impossible to predict the magnitude of these losses or the impact they will have on the earth and

its **future generations**, it is clear that the results will be profound, possibly catastrophic. In his book, *Disappearing Species: The Social Challenge*, Eric Eckholm of the **Worldwatch Institute** observed that humans, in their ignorance, have changed the natural course of **evolution** with current mass-extinction rates. "Should this biological massacre take place, evolution will no doubt continue, but in a grossly distorted manner. Such a multitude of species losses would constitute a basic and irreversible alteration in the nature of the **biosphere** even before we understand its workings..."

Eckholm further notes that when a plant species is wiped out, some 10 to 30 dependent species, such as insects and even other plants, can also be jeopardized. An example of the complex relationship that has evolved between many tropical species is the 40 different kinds of fig trees native to Central America, each of which has a specific insect pollinator. Other insects, including pollinators of other plants, depend on these trees for food. Thus, the extinction of one species can set off a **chain reaction**, the ultimate effects of which cannot be foreseen.

Although scientists know that human life will be harmed by these losses, the weight of the impact is unclear. As the **Council on Environmental Quality** states in its book *The Global Environment and Basic Human Needs*, over the next decade or two, "unique ecosystems populated by thousands of unrecorded plant and animal species face rapid destruction—irreversible genetic losses that will profoundly alter the course of evolution." This report also cautions that species extinction entails the loss of many useful products. Perhaps the greatest industrial, agricultural and medical costs of species reduction will stem from future opportunities unknowingly lost. Only about 5% of the world's plant species have yet been screened for pharmacologically active ingredients. Ninety percent of the food that humans eat comes from just 12 crops, but scores of thousands of plants are edible, and some will undoubtedly prove useful in meeting human food needs. *See also* Biodiversity; Climate; Dodo; Endangered species

Exxon Valdez

On March 24, 1989, the 987-foot super tanker *Exxon Valdez* outbound from Port Valdez, Alaska, with a full load of oil from Alaska's Prudhoe Bay passed on the wrong side of a lighted channel marker guarding a shallow stretch of **Prince William Sound**. The momentum of the large ship carried it onto Bligh Reef and opened a 6 x 20 ft hole in the ship's hull. Through this hole poured 257,000 barrels (11 million gallons) of crude oil, approximately 21% of the ship's 1.26 million barrel (53 million gallon) cargo, making it the largest oil spill in the history of the United States.

The oil spill resulting from the *Exxon Valdez* accident spread 38,0000 metric tonnes of oil along 1,500 miles of pristine shoreline on Prince William Sound and the Kenai Peninsula, covering an area of 460 miles. Oil would eventually reach shores southwest of the spill up to 600 miles away.

The *Exxon Valdez* Oil Spill Trustee Council estimates that 250,000 seabirds, 2,800 sea otters, 300 harbor **seals**, 250 bald eagles, and 22 killer **whales**, were killed. These figures may be an underestimate of the animals killed by the oil because many of the carcasses likely sank or washed out to sea before they could be collected. Most of the birds died from hypothermia due to the loss of insulation caused by oil-soaked feathers. Many predatory birds, such as bald eagles, died as a result of ingesting contaminated fish and birds. Hypothermia affected sea otters as well, and many of the dead mammals suffered lung damage due to oil fumes. Billions of **salmon** eggs were also lost to the spill. While a record 43 million pink salmon were caught in Prince William Sound in 1990, by 1993 the harvest had declined to a record low of three million.

Response to the oil spill was slow and generally ineffective. The Alyeska Oil Spill Team responsible for cleaning up **oil spills** in the region took more than 24 hours to respond, despite previous assurances that they could mount a response in three hours. Much of the oil containment equipment was missing, broken, or barely operable. By the time oil containment and recovery equipment were in place, 42 million liters of oil had already spread over a large area. Ultimately, less than 10% of this oil was recovered, the remainder dispersing into the air, water, and **sediment** of Prince William Sound and adjacent sounds and fjords. Exxon reports spending a total of $2.2 billion to clean up the oil. Much of this money employed 10,000 people to clean up oil-fouled beaches; yet after the first year, only 3% of the soiled beaches had been cleaned.

In response to public concern about the poor response time and uncoordinated initial cleanup efforts following the Valdez spill, the Oil **Pollution** Act (OPA; part of the **Clean Water Act**) was signed into law in August 1990. The Act

After hitting Bligh Reef on March 24, 1989, the *Exxon Valdez* sits near Naked Island, Alaska, swirls of crude oil surrounding the ship. Containment booms can be seen attached to the ship. (AP/Wide World Photos. Reproduced by permission.)

established a Federal trust fund to finance clean-up efforts for up to $1 billion per spill incident.

Ultimately, **nature** was the most effective surface cleaner of beaches; winter storms removed the majority of oil and by the winter of 1990, less than 6 miles (10 km) of shoreline was considered seriously fouled. Cleanup efforts were declared complete by the U.S. Coast Guard and the State of Alaska in 1992.

On October 9, 1991, a settlement between Exxon and the State of Alaska and the United States government was approved by the U.S. District Court. Under the terms of the agreement, Exxon agreed to pay $900 million in civil penalties over a 10-year period. The civil settlement also provides for a window of time for new claims to be made should unforeseen environmental issues arise. That window is from September 1, 2002 to September 1, 2006.

Exxon was also fined $150 million in a criminal plea agreement, of which $125 million was forgiven in return for the company's cooperation in cleanup and various private settlements. Exxon also paid $100 million in criminal restitution for the environmental damage caused by the spill.

A flood of private suits against Exxon have also deluged the courts in the years since the spill. In 1994, a district court ordered Exxon to pay $287 million in compensatory damages to a group of commercial fishermen and other Alaskan natives who were negatively impacted by the spill. The jury who heard the case also awarded the plaintiffs $5 billion in punitive damages. However, in November 2001 a federal appeals judge overturned the $5 billion punitive award, deeming it excessive and ordering the district court to reevaluate the settlement. As of May 2002, the final punitive settlement had not been determined.

The Captain of the *Exxon Valdez*, Joseph Hazelwood, had admitted to drinking alcohol the night the accident occurred, and had a known history of alcohol abuse. Nevertheless, he was found not guilty of charges that he operated a shipping vessel under the influence of alcohol. He was found guilty of negligent **discharge** of oil, fined $50,000, and sentenced to 1,000 hours of community service work.

Despite official cleanup efforts by Exxon having ended, the environmental legacy of the *Valdez* spill lives on. The Auke Bay Laboratory of the Alaskan Fisheries Science Center conducted a beach study of Prince William Sound in the summer of 2001. Researchers found that approximately 20 acres of Sound shoreline is still contaminated with oil, the majority of which has collected below the surface of the beaches where it continues to pose a danger to **wildlife**. Of the 30 **species** of wildlife affected by the spill, only two—the American **bald eagle** and the river otter— were considered recovered in 1999. Preliminary 2002 reports from the Exxon Valdez Oil Spill Trustee Council reflect progress is being made in the area of wildlife recovery, however, black oystercatchers, common murres, killer whales, subtidal communities, sockeye salmon, and pink salmon are all classified as recovered in the April draft of the organization's "Update on Injured Resources and Services," bringing the total recovered species to eight.

Family planning

The exaxt population of the world is unknown but believed at about 6.2 billion; it continues in its unrelenting growth especially in developing countries. Worldwide **famine** has been postponed thanks to modern agricultural procedures, known as the Green Revolution, which have greatly increased grain production. Nevertheless, with limited land and resources that can be devoted to food production—and increasing numbers of humans who need both space and food—there appears to be a significant risk of catastrophe by overpopulation. Because of this, there is increased interest in family planning. Family planning in this context means birth control to limit family size.

The subject of "family planning" is not limited to birth control but includes procedures designed to overcome difficulties in becoming pregnant. About 15% of couples are unable to conceive children after a year of sexual activity without using birth control. Many couples feel an intense desire and need to conceive children. Aid to these couples is thus a reasonable part of family planning. However, for most discussions of family planning, the emphasis is on limitation of family size, not augmentation.

Birth control procedures have evolved rapidly in this century. Further, utilization of existing procedures is changing with different age groups and different populations. Thus any account of birth control is likely to become rapidly obsolete. An example of the changing technology includes oral contraception with pills containing hormones. Birth control pills have been marketed in the United States since the 1960s. Since that time there have been many formulations with significant reductions in dosage. There was much greater acceptance of pills by American women under the age of 30. The intrauterine device (IUD) was much more popular in Sweden than in the United States whereas sterilization was more common in the United States than in Sweden.

A very common form of birth control is the condom, which is a thin **rubber** sheath worn by men during sexual intercourse. They are generally readily accessible, cheap, and convenient for those individuals who may not have sexual relations regularly. Sperm cannot penetrate the thin (0.3—0.8 mm thick) latex. Neither the human immunodeficiency **virus** (HIV) associated with **AIDS** nor the other pathogenic agents of sexually transmitted diseases (STDs) are able to penetrate the latex barrier. Some individuals are opposed to treating healthy bodies with drugs (hormones) for birth control, and for these individuals, condoms have a special appeal. Natural "skin" (lamb's intestine) condoms are still available for individuals who may be allergic to latex, but this product provides less protection to HIV and other STDs.

The reported failure rate of condoms is high and is most likely due to improper use. Yet during the Great Depression in the 1930s—when pills and other contemporary birth control procedures were not available—it is thought that the proper use of condoms caused the birth rate in the United States to plummet.

Spermicides—surface active agents which inactivate sperm and STD pathogens—can be placed in the vagina in jellies, foam, and suppositories. Condoms used in conjunction with spermicides have a failure rate lower than either method used alone and may provide added protection against some infectious agents.

Types of Contraceptives

Effectiveness	Predicted (%)	Actual (%)
Birth control pills	99.9	97
Condoms	98	88
Depo Provera	99.7	99.7
Diaphragm	94	82
IUDS	99.2	97
Norplant	99.7	99.7
Tubal sterilization	99.8	99.6
Spermicides	97	79
Vasectomy	99.9	99.9

The vaginal diaphragm, like the condom, is another form of barrier. The diaphragm was in use in World War I and was still used by about one third of couples by the time of World War II. However, because of the efficacy and ease of use of oral contraceptives, and perhaps because of the protection against disease by condoms, the use of vaginal diaphragms is down. The diaphragm, which must be fitted by a physician, is designed to prevent sperm access to the cervix and upper reproductive tract. It is used in conjunction with spermicides. Other similar barriers include the cervical cap and the contraceptive sponge. The cervical cap is smaller than the diaphragm and fits only around that portion of the uterus that protrudes into the vagina. The contraceptive sponge, which contains a spermicide, is inserted into the vagina prior to sexual intercourse and retained for several hours afterwards to insure that no living sperm remain.

Intrauterine devices (IUDs) were popular during the 1960s and 1970s in the United States, but their use today has dwindled. However in China, a nation which is rapidly attending to its population problems, about 60 million women use IUDs. The failure rate of IUDs in **less developed countries** is reported to be less than that with the pill. The devices may be plastic, **copper**, or stainless steel. The plastic versions may be impregnated with barium sulfate to permit visualization by x ray and also may slowly release hormones such as progesterone. Ovulation continues with IUD use. Efficacy probably results from a changed uterine **environment** which kills sperm.

Oral contraception is by means of the "pill." Pills contain an estrogen and a progestational agent, and current dosage is very low compared with several decades ago. The combination of these two agents is taken daily for three weeks followed by one week with neither hormone. Frequently a drug-free pill is taken for the last week to maintain the pill-taking habit and thus enhance the efficacy of the regimen. The estrogenic component prevents follicle maturation, and the progestational component prevents ovulation. Pill-taking women who have multiple sexual partners may wish to consider the addition of a barrier method to minimize risk for STDs. The reliability of the pill reduces the need for abortion or surgical sterilization. There may be other salutary health effects which include less endometrial and ovarian **cancer** as well as fewer uterine fibroids. Use of oral contraceptives in women over the age of 35 who also **smoke** is thought to increase the risk of heart and vascular disease.

Contraceptive hormones can be administered by routes other than oral. Subdermal implants of progestin-containing tubules have been available since 1990 in the United States. In this device familiarly known as Norplant, six tubules are surgically placed on the inside of the upper arm, and the hormone diffuses through the wall of the tubules to provide long term contraceptive activity. Another form of progestin-only contraception is by intramuscular injection which must be repeated every three months.

Fears engendered by IUD litigation are thought to have increased the reliance of many American women on surgical sterilization (tubal occlusion). Whatever the reason, more American women rely on the procedure than do their European counterparts. Tubal occlusion involves the mechanical disruption of the oviduct, the tube that leads from the ovary to the uterus, and prevents sperm from reaching the egg. Inasmuch as the fatality rate for the procedure is lower than that of childbirth, surgical sterilization is now the safest method of birth control. Tubal occlusion is far more common now that it was in the 1960s because of the lower cost and reduced surgical stress. Use of the laparoscope and very small incisions into the abdomen have allowed the procedure to be completed during an office visit.

Male sterilization, another method, involves severing the vas deferens, the tube that carries sperm from the testes to the penis. Sperm comprise only a small portion of the ejaculate volume, and thus ejaculation is little changed after vasectomy. The male hormone is produced by the testes and production of that hormone continues as does erection and orgasm.

Most abortions would be unnecessary if proper birth control measures were followed. That of course is not always the case. Legal abortion has become one of the leading surgical procedures in the United States. Morbidity and **mortality** associated with pregnancy have been reduced more with legal abortion than with any other event since the introduction of antibiotics to fight puerperal fever.

Other methods of birth control are used by individuals who do not wish to use mechanical barriers, devices, or drugs (hormones). One of the oldest of these methods is

withdrawal (*coitus interruptus*), in which the penis is removed from the vagina just before ejaculation. Withdrawal must be exquisitely timed, is probably frustrating to both partners, is not thought to be reliable, and provides no protection against HIV and other STD infections. Another barrier-and-drug-free procedure is natural family planning (also known as the rhythm method). Abstinence of sexual intercourse is scheduled for a period of time before and after ovulation. Ovulation is calculated by temperature change, careful record keeping of menstruation (the calendar method), or by vaginal mucous inspection. Natural family planning has appeal for individuals who wish to limit their exposure to drugs, but it provides no protection against HIV and other STDs.

The population of the world increases by about 140 million every year, while the world is unable to sustain its new residents adequately. That increase signals the need for family planning education and the continued development of ever more efficient birth control methods. *See also* Population Council; Population growth; Population Institute

Famine

Famine is widespread hunger and starvation. A region struck with famine experiences acute shortages of food, massive loss of lives, social disruption, and economic chaos. Images of starving mothers and children with emaciated eyes and swollen bellies during recent crises in Ethiopia and Somalia have brought international attention to the problem of famine. Other well-known famines include the great Irish potato famines of the 1850s that drove millions of immigrants to America, and a Russian famine during Stalin's **agricultural revolution** that killed 20 million people in the 1930s. The worst recorded famine in recent history occurred in China between 1958 and 1961, when 23–30 million people died as a result of the failed agricultural program, "the great leap forward."

Even though we may think of these tragedies as single, isolated events, famine, and chronic hunger continue to be serious problems. Between 18 and 20 million people, three-quarters of them children, die each year of starvation or diseases caused by malnourishment. How can this be? Environmental problems like overpopulation, scarce resources, and natural disasters affect people's ability to produce food. Political and economic problems like unequal distribution of wealth, delayed or insufficient action by local governments, and imbalanced trade relationships between countries affect people's ability to buy food when they cannot produce it.

Perhaps the most common explanation for famine is overpopulation. The world's population, now more than 6.2 billion people, grows by 250,000 people every day. It seems impossible that the natural world could support such rapid growth. Indeed, the pressures of rapid growth have had a devastating impact on the **environment** in many places. Land that once fed one family must now feed 10 families and resulting over-use harms the quality of the land. The world's deserts are rapidly expanding as people destroy fragile **topsoil** by poor farming techniques, clearing vegetation, and **overgrazing**.

Although the demands of **population growth** and industrialization are straining our environment, we have yet to exceed the limits of growth. Since the 1800s some have predicted that humans, like rabbits living without predators, would foolishly reproduce far beyond the **carrying capacity** of their environment and then die in masses from lack of food. This argument assumes that the supply of food will remain the same as populations grow, but as populations have grown, people have learned to grow more food. World food production increased two-and-a-half times between 1950 and 1980. Alter World War II, agriculture specialists caused a "green revolution," developing new crops and farming techniques that radically increased food production per acre. Farmers began to use special hybrid crop strains, chemical fertilizers, pesticides, and advanced **irrigation** systems. Today, there is more than enough food available to feed everyone. In fact, the United States government spends billions of dollars every year to store excess grain and to keep farmers from farming portions of their land.

Many famines occur in the aftermath of natural disasters like floods and droughts. In times of **drought**, crops cannot grow because they do not have enough water. In times of flood, excess water washes out fields, destroying crops and disrupting farm activity. These disasters have several effects. First, damaged crops cause food shortages, making nutrients difficult to find and making any food available too expensive for many people. Second, reduced food production means less work for those who rely on temporary farm work for their income. Famines usually affect only the poorest five to ten percent of a country's population. They are most vulnerable because during a crisis wages for the poorest workers go down as food prices go up.

Famine is a problem of distribution as well as production. Environmental, economic, and political factors together determine the supply and distribution of food in a

country. Starvation occurs when people lose their ability to obtain food by growing it or by buying it. Often, poor decisions and organizations aggravate environmental factors to cause human suffering. In Bangladesh, floods during the summer of 1974 interfered with rice transplantation, the planting of small rice seedlings in their rice patties. Although the crop was only partly damaged, speculators hoarded rice, and fears of a shortage drove prices beyond the reach of the poorest in Bangladesh. At the same time, disruption of the planting meant lost work for the same people. Even though there was plenty of rice from the previous year's harvest, deaths from starvation rose as the price of rice went up. In December of 1974, when the damaged rice crop was harvested, the country found that its crop had been only partly ruined. Starvation resulted not from a shortage of rice, but from price speculation. The famine could have been avoided completely if the government had responded more quickly, acting to stabilize the rice market and to provide relief for famine victims.

In other cases, governments have acted to avoid famine. The Indian state of Maharahtra offset affects of a severe drought in 1972 by hiring the poorest people to work on public projects like roads and **wells**. This provided a service for the country and at the same time diverted a catastrophe by providing an income for the most vulnerable citizens to compete with the rest of the population for a limited food supply. At the same time, the countries of Mali, Niger, Chad, and Senegal experienced severe famine, even though the average amount of food per person in these countries was the same as in Maharahtra. The difference, it would seem, lies in the actions and intentions of the governments. The Indian government provides a powerful example. Although India lags behind many countries in economic development, education, and health care, the Indians have managed to avert serious famine since 1943, four years before they gained independence from the British.

Responsibility for hunger and famine rests also with the international community. Countries and peoples of the world are increasingly interconnected, continuously exchanging goods and services. We are more and more dependent on one another for success and for survival. The world economic and political order dramatically favors the wealthiest industrialized countries, in Europe and North America. Following patterns established during colonial expansion, **Third World** nations often produce raw materials, unfinished goods, and basic commodities like bananas and coffee that they sell to the **First World** at low prices. The First World nations then manufacture and refine these products and sell back information and technology, like machinery and computers for a very high price. As a result, the wealthiest nations amass capital and resources, and enjoy very high standards of living, while the poorest nations retain huge national debts and struggle to remain stable economically and politically. The word's poorest countries, then, are left vulnerable to all of the conditions which cause famine, economic hardship, political instability, overpopulation, and over-taxed resources.

Furthermore, large colonial powers often left behind unjust political and social hierarchies that are very good at extracting resources and sending them north, but not as good at promoting social justice and human welfare. Many Third World countries are dominated by a small ruling class who own most of the land, control industry, and run the government. Since the poorest people, who suffer most in famines, have little power to influence government policies and manage the countries economy, their needs are often unheard and unmet. A government that rules without democratic support of its people has less incentive to protect those who would suffer in times of famine. In addition, the poorest often do not benefit from the industry and agriculture that does exist in a developing country. Large corporate farms often force small subsistence farmers off of their land. These farmers must then work for day wages, producing food for export, while local people go without adequate nutrition.

Economic and social arrangements, as well as environmental conditions, are central to the problems of hunger and starvation. Famine is much less likely to occur in countries that are concerned with issues of social justice. In the same way, famine is much less likely to occur in a world that is concerned with issues of social justice. Environmental pressures of population growth and human use of **natural resources** will continue to be issues of great concern. Natural disasters like droughts and floods will continue to occur. The best response to the problem of famine lies in working to better manage **environmental resources** and crisis situations and to change political and economic structures that cause people to go without food.

Fauna

All animal life that lives in a particular geographic area during a particular time in history. The type of fauna to be found in any particular region is determined by factors such as plant life, physical **environment**, topographic barriers, and evolutionary history. Zoologists sometimes divide the earth into six regions inhabited by distinct faunas: Ethiopian (Africa south of the Sahara, **Madagascar**, Arabia), Neotropical (South and Central America, part of Mexico, the West Indies), Australian (**Australia**, New Zealand, New Guinea), Oriental (Asia south of the Himalaya Mountains, India, Sri Lanka, Malay Peninsula, southern China, Borneo, Sumatra, Java, the Philippines), Palearctic (Europe, Asia north of the Himalaya Mountains, Afghanistan, Iran, North Africa), and Nearctic (North America as far south as southern Mexico).

Fecundity

Fecundity comes from the Latin word *fecundus*, meaning fruitful, rich, or abundant. It is the rate at which individual organisms in the population produce offspring. Although the term can apply to plants, it is typically restricted to animals.

There are two aspects of reproduction: 1) fertility, referring to the physiological ability to breed, and 2) fecundity, referring to the ecological ability to produce offspring. Thus, higher fecundity is dependent on advantageous conditions in the **environment** that favor reproduction (e.g., abundant food, space, water and mates; limited predation, parasitism, and **competition**). The intrinsic rate of increase (denoted as "r") equals the birth rate minus the death rate. It is a population characteristic that takes into account that not all individuals have equal birth rates and death rates. It therefore refers to the reproductive capacity in the population made up of individual organisms. Fecundity, on the other hand, is an individual characteristic. It can be further subdivided into potential and realized fecundity. For example, deer can potentially produce four or more fawns per year, but they typically give birth to only one or two per year. In good years with ample food, they often have only two fawns.

Animals in **nature** are limited by environmental conditions that control their life history characteristics such as birth, **survivorship**, and death. A graph of the number of offspring per female per age class (e.g., year) is a fecundity curve. This can then be used to interpret the individuals of a certain age class who contribute more to the **population growth** than others. In other words, certain age classes have a greater reproductive output than others. **Wildlife** managers often use this type of information in deciding which individuals in a population can be hunted verses those that should be protected so they can reproduce.

As the number of animals increase, competition for food may become more intense and, therefore, growth and reproduction may decrease. The result is an example of density-dependent fecundity. Fecundity in predators typically increases with an increase in the prey population. Conversely, fecundity in prey **species** typically increases when predation pressure is low.

Some scientists have found that fecundity is inversely related to the amount of parental care given to the young. In other words, small organisms such as insects and fish which typically invest less time and energy into caring for the young usually have higher fecundity. Larger organisms such as birds and mammals which expend a lot of energy on caring for the young through building of nests, feeding, protecting, and caring have lower fecundity rates.

Federal Energy Regulatory Commission

The Federal Energy Regulatory Commission (FERC) is an independent, five-member commission within the **U.S. Department of Energy**. The Commission was created in October 1977 as a part of the Federal government's mammoth effort to restructure and reorganize its energy program. The Commission was assigned many of the functions earlier assigned to the **Federal Power Commission** (FPC).

The Federal Power Commission had existed since 1920 when it was created to license and regulate hydroelectric **power plants** situated on interstate streams and rivers. Over the next half century, the Power Commission was assigned more and more responsibility for the management of United States energy reserves. In the Public Utilities Holding Company Act of 1935, for example, Congress gave to the Commission responsibility for setting rates for the wholesale pricing of electricity shipped across state lines. FPC's mission was expanded even further in the 1935 Natural Gas Act. That act gave the Commission the task of regulating the nation's natural gas pipelines and setting rates for the sale of **natural gas**.

Regulating energy prices in the pre-1970s era was a very different problem than it is in the 1990s. That era was one of abundant, inexpensive energy. Producers, consumers and regulators consistently dealt with a surplus of energy. There was more energy of almost any kind than could be consumed. That situation began to change in the early 1970s, especially after the **oil embargo** instituted by the **Organization of Petroleum Exporting Countries** in 1973. The resulting energy crisis caused the United States government to re-think carefully its policies and practices regarding energy production and use.

One of the studies that came out of that re-analysis was the 1974 Federal Energy Regulation Study Team report. The team found a number of problems in the way energy was managed in the United States. They reported that large gaps existed in some areas of regulation, with no agency responsible, while other areas were characterized by overlaps, with two, three, or more agencies all having some responsibility for a single area. The team also found that regulatory agencies were more oriented to the past than to current problems or future prospects, worked with incomplete or inaccurate date, and employed procedures that were too lengthy and drawn out.

As one part of the Department of Energy Organization Act of 1977, then, the FPC was abolished and replaced by the Federal Energy Regulatory Commission. The Commission is now responsible for setting rates and charges for the **transportation** and sale of natural gas and for the transmission and sale of electricity. It continues the FPC's old responsibility for the licensing of hydroelectric plants.

In addition, the Commission has also been assigned responsibility for establishing the rates for the transportation of oil by pipelines as well as determining the value of the pipe lines themselves. Overall, the Commission now controls the pricing of 60% of all the natural gas and 30% of all the electricity in the United States.

Ordinary citizens sometimes do not realize the power and influence of independent commissions like the FERC. But they can have significant impact on federal policy and practice. As one writer has said, "While Energy Secretaries come and go, and Congress can do little more than hold hearings, the five-member FERC is making national **energy policy** by itself."

Federal Insecticide, Fungicide and Rodenticide Act (1972)

The **Environmental Protection Agency** (EPA) is the primary regulatory agency of pesticides. The EPA's authority on pesticides is given in the Congressionally-enacted Federal Insecticide, **Fungicide** and Rodenticide Act (FIFRA)—a comprehensive regulatory program for pesticides and herbicides enacted in 1972 and amended nearly 50 times over the years. The goal of FIFRA is to regulate the use of pesticides through registration.

Section 3 of FIFRA mandates that the EPA must first determine that the product "will perform its intended function without unreasonable adverse effects on the environment" before it is registered. The Act defines adverse effects as "any unreasonable effects on man or the **environment**, taking into account the economic, social and environmental costs and benefits of using any pesticide." To further this objective, Congress placed a number of regulatory tools at the disposal of the EPA. Congress also made clear that the public was not to bear the risk of uncertainty concerning the safety of a **pesticide**. To grant registration, the EPA must conclude that the food production benefits of a pesticide outweigh any risks.

To make the cost-benefit determination required to register a pesticide as usable, manufacturers must submit to EPA detailed tests on the chemical's health and environmental effects. The burden rests on the manufacturer to provide the data needed to support registration for use on a particular crop. The pesticide manufacturer is required to submit certain health and safety data to establish that the use of the pesticide will not generally cause unreasonable adverse effects. Data required include disclosure of the substance's chemical and toxicological properties, likely distribution in the environment, and possible effects on **wildlife**, plants, and other elements in the environment.

FIFRA is a licensing law. Pesticides may enter commerce only after they are approved or "registered following an evaluation against statutory risk/benefit standards." The Administrator may take action to terminate any approval whenever it appears, on the basis of new information or a re-evaluation of information, that the pesticide no longer meets the statutory standard. These decisions are made on a use-by-use basis since the risks and benefits of a pesticide vary from one use to another.

FIFRA is also a control law. Special precautions and instructions may be imposed. For example, pesticide applicators may be required to wear protective clothing, or the use of certain pesticides may be restricted to trained and certified applicators. Instructions, warnings, and prohibitions are incorporated into product labels, and these labels may not be altered or removed.

FIFRA embodies the philosophy that those who would benefit by government approval of a pesticide product should bear the **burden of proof** that their product will not pose unreasonable risks. This burden of proof applies both when initial marketing approval is sought and in any proceeding initiated by the Administrator to interrupt or terminate registration through suspension or cancellation. Of course, while putting the burden on industry, the assumption is that industry will be honest in its research and reports.

Licensing decisions are usually based on tests furnished by an applicant for registration. The tests are performed by the petitioning company in accordance with testing guidelines prescribed by the EPA. Requirements for the testing of pesticides for major use can be met only through the expenditure of several millions of dollars and up to four years of laboratory and field testing.

However, major changes in test standards, advances in testing methodology, and the heightened awareness of the potential chronic health effects of long-term, low-level exposure to **chemicals** which have come into the marketplace within the past several decades have brought the need to update EPA mandates. Thus, Congress directed that the EPA reevaluate its licensing decisions through a process of re-registration. That means if the government once approved a certain product for domestic use, it does not mean the EPA can be confident today that its use can continue.

The EPA has the power to suspend or cancel products. Cancellation means the product in question is no longer considered safe. It must be taken off the commercial market and is no longer available for use. Suspension means the product in question is not to be sold or used under certain conditions or in certain places. This may be a temporary decision, usually dependent on further studies.

There may be certain products that, in the opinion of the administrator, may be harmful. But no action is taken if and when the action is incompatible with administration priorities. That is because the EPA administrator is responsible to the directives and priorities of the President and the executive branch. Thus, some regulatory decisions are political.

There is a statutory way to avoid the re-registration process. It is called Section 18. Section 18 under FIFRA allows for the use of unregistered pesticides in certain emergency situations. It provides that "the Administrator may, at his discretion, exempt any Federal or State agency from any provisions of this subchapter if he determines that emergency conditions exist which requires such exemption. The Administrator, in determining whether or not such emergency conditions exist, shall consult with the Secretary of Agriculture and the Governor of any state concerned if they request such determination."

From 1978 to 1983, the General Accounting Office (GAO) and the House Subcommittee on Department Operations, Research and Foreign Agriculture of the Committee on Agriculture (DORFA Subcommittee) thoroughly examined the EPA's implementation of Section 18. Under the auspices of Chair George E. Brown, Jr., (D-CA) the DORFA Subcommittee held a series of hearings which revealed numerous abuses in EPA's administration of Section 18. A report was issued in 1982 and reprinted as part of the Committee's 1983 Hearings.

The Subcommittee found that "the rapid increase in the number and volume of pesticides applied under Section 18 was clearly the most pronounced trend in the EPA's pesticide regulatory program." According to the Subcommittee report, "a primary cause of the increase in the number of Section 18 exemptions derived from the difficulty the Agency had in registering chemicals under Section 3 of FIFRA in a timely manner." The DORFA committee stated: "Regulatory actions involving suspect human carcinogens which meet or exceed the statute's "unreasonable adverse effects" criterion for chronic toxicity often become stalled in the Section 3 review process for several years. The **risk assessment** procedures required by States requesting Section 18 actions, and by EPA in approving them, are generally less strict. For example, a relatively new insecticide, first widely used in 1977, was granted some 140 Section 18 emergency exemptions and over 300 (Section 24c) Special Local Needs registrations in the next four years while the Agency debated the significance to man of positive evidence of oncogenicity in laboratory animals."

The EPA's practices changed little over the next eight years. In the spring of 1990, the Subcommittee on Environment of the House Science, Space and Technology Committee (Chair: James H. Scheuer, D-NY) investigated the EPA's procedures under Section 18 of FIFRA and found if anything, the problem had gotten worse. The report states: "Since 1973, more than 4,000 emergency exemptions have been granted for the use of pesticides on crops for which there is no registration." A large number of these emergency exemptions have been repeatedly granted for the same uses for anywhere from fourteen, to ten, to eight, to five years. The House Subcommittee also found that the EPA required less stringent testing procedures for pesticides under the exemption, which put companies that follow the normal procedure at a disadvantage. The Subcommittee concluded that the large numbers of emergency exemptions arose from "the EPA's failure to implement its own regulations."

The Subcommittee identified "emergencies" as "routine predicted outbreaks and foreign competition" and "a company's need to gain market access for use of a pesticide on a new crop, although the company often never intends to submit adequate data to register the chemical for use."

As for the re-registration requirement, the Subcommittee observed: "The EPA's reliance on Section 18 may be related to the Agency's difficulty in re-registering older chemical substances. Often, Section 18 requests are made for the use of older chemicals on crops for which they are not registered. These older chemicals receive repetitive exemptions for use despite the fact that many of these substances may have difficulty obtaining re-registration since they have been identified as potentially carcinogenic. Thus, by liberally and repetitively granting exemptions to potentially carcinogenic substances, little incentive is provided to encourage companies to invest in the development of newer, safer pesticides or alternative agricultural practices."

The report concluded, "...Allowing these exemptions year after year in predictable situations provides 'back-door' pre-registration market access to potentially dangerous chemicals." *See also* Environmental law; Integrated pest management; National Coalition Against the Misuse of Pesticides; Pesticide Action Network; Risk analysis

Federal Land Policy and Management Act (1976)

The Federal Land Policy and Management Act (FLPMA), passed in 1976, is the statutory grounding for the **Bureau of Land Management** (BLM), giving the agency authority and direction for the management of its lands. The initiative leading to the passage of FLPMA can be traced to the BLM itself. The agency was concerned about its insecure status—it was formed by executive reorganization rather than by a congressional act, it lacked a clear mandate for land management, and it was uncertain of the federal government's plans to retain the lands it managed. This final point can be traced to the **Taylor Grazing Act**, which included a clause that these public lands would be managed for grazing "pending final disposal." The BLM wanted a law that would address each of these issues, so that the agency could undertake long-range, multiple use planning like their colleagues in the **Forest Service**.

Agency officials drafted the first "organic act" in 1961, but two laws passed in 1964 served to really get the legislative process moving. The **Public Land** Law Review Commission (PLLRC) Act established a commission to examine the body of public land laws and make recommendations as to how to proceed in this policy area. The Classification and Multiple Use Act instructed the BLM to inventory its lands and classify them for disposal or retention. This would be the first inventory of these lands and resources, and suggested that at least some of these lands would be retained in federal ownership.

The PLLRC issued its report in 1970. In the following years, Congress began to consider three general types of bills in response to the PLLRC report. The administration and the BLM supported a BLM organic act without additional major reforms of other public land laws. The second approach provided the BLM with an organic act, but also made significant revisions in the Mining Law of 1872 and included environmental safeguards for BLM activities. This variety of bill was supported by environmentalists. The final type of bill provided a general framework for more detailed legislation in the future. This general framework tended to support commodity production, and was favored by livestock, mining, and timber interests.

In 1973, a bill of the second variety, introduced by Henry Jackson of Washington, passed the Senate. A similar bill died in the House, though, when it was denied a rule, and hence a trip to the floor, by the Rules Committee. Jackson re-introduced a bill that was nearly identical to the bill previously passed, and the Senate passed this bill in February 1976. In the House, things did not move as quickly. The main House bill, drafted by four western members of the Interior and Insular Affairs Committee, included significant provisions dealing with grazing—most importantly, a provision to adopt a statutory grazing fee formula based upon beef prices and private forage cost. This bill had the support of commodity interests, but was opposed by the administration and environmental groups. The bill passed the full House by fourteen votes in July 1976.

The major differences that needed to be addressed in the conference committee included law enforcement, the grazing provisions, mining law provisions, wild horses and burros, unintentional trespass, and the California **Desert Conservation** Area. By late September, four main differences remained, three involving grazing, and one dealing with mining. For a period it appeared that the bill might die in committee, but final compromises on the grazing and mining issues were made and a bill emerged out of conference. The bill was signed into law in October 1976 by President Gerald Ford.

As passed, FLPMA dealt with four general issue areas: 1) the organic act sections, giving the BLM authority and direction for managing the lands under its control; 2) grazing policy; 3) preservation policy; and 4) mining policy. The act begins by stating that these lands will remain in public ownership: "The Congress declares that it is the policy of the United States that...the public lands be retained in public ownership." This represented the true, final closing of the public domain; the federal government would retain the vast majority of these lands. To underscore this point, FLPMA repealed hundreds of laws dealing with the public lands that were no longer relevant. The BLM, under the authority of the Secretary of the Interior, was authorized to manage these lands for multiple use and sustained yield and was required to develop **land use** plans and resource inventories for the lands based on long-range planning. A director of the BLM was to be appointed by the President, subject to confirmation by the Senate.

FLPMA limited the withdrawal authority of the Secretary, often used to close lands to mineral development or to protect them for other environmental reasons, by repealing many of the sources of this authority and limiting its uses in other cases. The act allowed for the sale of public lands under a set of guidelines. In a section of the law that received much attention, the BLM was authorized to enforce the law on the lands it managed. The agency was directed to cooperate with local law enforcement agencies as much as possible in this task. It was these agencies, and citizens who lived near BLM lands, who were skeptical of this new BLM enforcement power. Other important provisions of the law allowed for the capture, removal, and relocation of wild horses and burros from BLM lands and authorized the Secretary of the Interior to grant rights-of-way across these lands for most pipelines and electrical **transmission lines**.

The controversial grazing fee formula in the House bill, favored by the livestock industry, was dropped in the conference committee. In its place, FLPMA froze grazing fees at the 1976 level for one year and directed the Secretaries of Agriculture and the Interior to undertake a comprehensive study of the grazing fee issue so that an equitable fee could be determined. This report was completed in 1977, and Congress established a statutory fee formula in 1978. That formula was only binding until 1985, though, and since that time Congress has debated the grazing fee issue numerous times, but the issue remains unsettled.

FLPMA also provided that grazing permits be for ten year periods, and that at least two year notice be given before permits were cancelled (except in an emergency). At the end of the ten year lease, if the lands are to remain in grazing, the current permittee has the first priority on renewing the lease to those lands. This virtually guarantees a rancher the use of certain public lands as long as they are to be used for grazing. The permittee is also to receive compensation for private improvements on public lands if the permit is cancelled. These provisions, advocated by livestock interests, further demonstrated their belief, and the belief of their supporters in Congress, that these grazing permits were a type of property right. Grazing advisory boards, originally started after the Taylor Grazing Act but terminated in the early 1970s, were resurrected. These boards consist of local grazing permittees in the area, and advise the BLM on the use of range improvement funds and on allotment management plans.

Important provisions regarding the preservation of BLM lands were also included in FLPMA. BLM lands were not covered in the **Wilderness Act** of 1964, and FLPMA dealt with this omission by directing that these lands be reviewed for potential **wilderness** designation, and that recommendations be made by the agency of which lands should be designated as wilderness. These designations would then be acted upon by Congress. This process is well underway. As has been the case with additions to the National Wilderness Preservation System on **national forest** lands since RARE II, BLM wilderness designation is being considered on a state-by-state basis. Thus far, a comprehensive wilderness designation law has only been passed for Arizona and California. Recent controversy has centered over the designation of wilderness in Utah.

FLPMA established a special California Desert Conservation Area, and directed the BLM to study this area and develop a long-range plan for its management. In 1994, after eight years of consideration, Congress passed the California Desert Protection Act. Senator Dianne Feinstein of California played the major role in guiding the legislation to passage, including overcoming an opposition-led filibuster against the act in October. The act, which included a number of compromises with desert users, established two new national parks and a new national preserve as well as designating approximately 7.5 million acres (3 million ha) of California desert as wilderness (in the two parks, the preserve, and nearly 70 new wilderness areas). The new national parks were created by enlarging and upgrading the existing Death Valley and Joshua Tree National Monuments. The Mojave National Preserve was originally to be a third **national park** in the desert, but its status was reduced to a national preserve to allow continued **hunting**, a compromise that helped gain further support for the bill. This law protected more wilderness than any law since the 1980 Alaska Lands Act. The following year, however, there was a move to alter these provisions. As part of the 1996 fiscal year Interior Appropriations bill, Congress directed that the BLM—not the National Park Service—manage the new Mojave National Preserve. According to Republican supporters, the BLM would allow for more use of the land. President Clinton vetoed

this appropriations bill in December 1995, in part due to this change in California Desert management. When the final Interior Appropriations Act was passed in April 1996, it included a provision requiring the Park Service to manage the Mojave under the less restrictive BLM standards, but it also allowed the President to waive this provision. Clinton signed the bill, and then immediately waived the provision, so the Mojave is being managed by the **National Park Service** under its own standards.

FLPMA required that all mining claims, based on the 1872 Mining Law, be recorded with the BLM within three years. Claims not recorded were presumed abandoned. In the past, such claims only had to be recorded at the county courthouse in the county in which the claim was located. This allowed for increased knowledge about the number and location of such claims. The law also included amendments to the **Mineral Leasing Act** of 1920, increasing the share of the revenues from such leases that went to the states, allowing the states to spend these funds on any public facilities needed (rather than just roads and schools), and reducing the amount of revenues going to the fund to reclaim these mineral funds.

The implementation of FLPMA has been problematic. One consequence of the act, and the planning and management that it has required, was the stimulation of western hostility to the BLM and the existence of so much federal lands. According to a number of analysts, FLPMA was largely responsible for starting the **Sagebrush Rebellion**, the movement to have federal lands transferred to the states. The foremost implementation problems have been due to the poor bureaucratic capacity of the BLM: the lack of adequate funding, the lack of an adequate number of employees, poor standing within the **U.S. Department of the Interior** and presidential administrations, and its history of subservience to grazing and mining interests.

Federal Power Administration

see **U.S. Department of Energy**

Federal Power Commission

The Federal Power Commission was established June 23, 1930, under the authority of the Federal Water Power Act, which was passed on March 3, 1921. The commission was terminated on August 4, 1977, and its functions were transferred to the **Federal Energy Regulatory Commission** under the umbrella of the **U.S. Department of Energy**.

The most important function of the commission during its 57-year existence was the licensing of water-power projects. It also reviewed plans for water-development programs submitted by major federal construction agencies for conformance with the interests of public good. In addition, the commission retained responsibility for interstate regulation of **electric utilities** and the siting of hydroelectric **power plants** as well as their operation. It also set rates and charges for the **transportation** and sale of **natural gas** and electricity. The five members of the commission were appointed by the president with approval of the Senate; three of the members were the Secretaries of the Interior, Agriculture, and War (later designated as U.S. Department of the Army). The commission retained its status as an independent regulatory agency for decision making, which is considered necessary for national security purposes.

Feedlot runoff

Feedlots are containment areas used to raise large numbers of animals to an optimum weight within the shortest time span possible. Most feedlots are open air, and are thereby subject to variable weather conditions. A substantial portion of the feed is not converted into meat, and is excreted, thus degrading the air, ground, and surface **water quality**. The issues of odor and **water pollution** from such facilities center on the traditional attitudes of producers that farming has always produced odors, and manure is a **fertilizer**, not a waste from a commercial undertaking.

Animal excrement is indeed rich in nutrients, particularly **nitrogen**, **phosphorus**, and potassium. A single 1,300-lb (590 kg) steer will excrete about 150 lb (68 kg) of nitrogen; 50 lb (23 kg) of phosphorus; and 100 lb (45 kg) of potassium in the course of a year. That is almost as much **nutrient** as would be required to grow one acre of corn, which needs 185 lb (84 kg) of nitrogen; 80 lb (36 kg) of phosphorus; and 215 lb (98 lb) of potassium. Unfortunately, manure is costly to transport, difficult to apply, and its nutrient quality is inconsistent. Artificial fertilizers, on the other hand, offer

ease of application and storage and proven quality and plant growth.

Legislative and regulatory action have increased with encroachment of urban population and centers of high sensitivity, such as shopping malls and **recreation** facilities. Since odor is difficult to measure, control of these facilities is being achieved on the grounds that they must not pose a "nuisance," a principle that is being sustained by the courts.

Odor is influenced by feed, number and **species** of animal, lot surface and manure removal frequency, wind, humidity, and moisture. These factors, individually and collectively, influence the type of **decomposition** that will occur. Typically, it is an **anaerobic** process which produces a sharp pungent odor of ammonia, the nauseating odor of rotten eggs from **hydrogen** sulfide, and the smell of decaying cabbage or onions from methyl mercaptan.

Odorous compounds seldom reach concentrations that are dangerous to the public. However, levels can become dangerously elevated with reduced ventilation in winter months or during pit cleaning. It is this latter activity, in conjunction with disposal onto the surface of the land, that is most frequently the cause of complaints. Members of the public respond to feedlot odors depending on their individual sensitivity, previous experience, and disposition. It can curtail outdoor activities and require windows to be closed, which means the additional use of air purifiers or air-conditioning systems.

Surface water contamination is the problem most frequently attributed to open feedlot and manure spreading activities. It is due to the dissolving, eroding action of rain striking the manured-covered surface. Duration and intensity of rainfall dictates the concentration of contaminants that will flow into surface waters. Their dilution or retention in ponds, rivers, and streams depends on area **hydrology** (dry or wet conditions) and **topography** (rolling or steeply graded landscape). Such factors also influence conditions in those parts of the continent where precipitation is mainly in the form of snow. Large snow drifts form around wind breaks, and in the early spring, substantial volumes of snowmelt are generated.

Odor and water **pollution control** techniques include simple operational changes, such as increasing the frequency of removing manure, scarifying the surface to promote **aerobic** conditions, and applying disinfectants and feed-digestion supplements. Other control measures require construction of additional structures or the installation of equipment at feedlots. These measures include installing water spargelines, adding impervious surfaces, drains, pits and roofs, and installing extraction fans. *See also* Animal waste; Odor control

Feedlots

A feedlot is an open space where animals are fattened before slaughter. Beef cattle usually arrive at the feedlot directly from the ranch or farm where they were raised, while poultry and pigs often remain in an automated feedlot from birth until death. Feed (often grains, alfalfa, and molasses) is provided to the animals so they do not have to forage for their food. This feeding regimen promotes the production of higher quality meat more rapidly. There are no standard parameters for the number of animals per acre in a feedlot, but the density of animals is usually very high. Some feedlots can contain 100,000 cows and steers. **Animal rights** groups actively campaign against confining animals in feedlots, a practice they consider inhumane, wasteful, and highly polluting.

Feedlots were first introduced in California in the 1940s, but many are now found in the Midwest, closer to grain supplies. Feedlot operations are highly mechanized and large numbers of animals can be handled with relatively low labor input. About half of the beef produced in the United States is feedlot-raised.

Feedlots are a significant **nonpoint source** of the **pollution** flowing into surface waters and **groundwater** in the United States. At least half a billion tons of **animal waste** are produced in feedlots each year. Since this waste is concentrated in the feedlot rather than scattered over grazing lands, it overwhelms the soil's ability to absorb and **buffer** it and creates nitrate-rich, bacteria-laden **runoff** to pollute streams, rivers, and lakes. Dissolved pollutants can also migrate down through the **soil** into aquifers, leading to **groundwater pollution** over wide areas. To protect surface waters, most states require that **feedlot runoff** be collected. However, protection of groundwater has proved to be a more difficult problem, and successful regulatory and technological controls have not yet been developed.

Fertilizer

Any substance that is applied to land to encourage plant growth and produce higher crop yield. Fertilizers may be made from organic material—such as recycled waste, animal manure, compost, etc.—or chemically manufactured. Most fertilizers contain varying amounts of **nitrogen**, **phosphorus**, and potassium, inorganic nutrients that plants need to grow.

Since the 1950s crop production worldwide has increased dramatically because of the use of fertilizers. In combination with the use of pesticides and insecticides, fertilizers have vastly improved the quality and yield of such crops as corn, rice, wheat, and cotton. However overuse and improper use of fertilizers have also damaged the **environment** and affected the health of humans, animals, and plants.

In the United States, it is estimated that as much as 25% of fertilizer is carried away as **runoff**. Fertilizer runoff has contaminated **groundwater** and polluted bodies of water near and around farmlands. High and unsafe nitrate concentrations in drinking water have been reported in countries that practice intense farming, including the United States. Accumulation of nitrogen and phosphorus in waterways from chemical fertilizers has also contributed to the eutrophication of lakes and ponds. Ammonia, released from the decay of fertilizers, causes minor irritation to the respiratory system.

While very few advocate the complete eradication of chemical fertilizers, many environmentalists and scientists urge more efficient ways of using them. For example, some farmers use up to 40% more fertilizer than they need. Frugal applications—in small doses and on an as-needed-basis on specific crops—helps reduce fertilizer waste and runoff. The use of organic fertilizers, including **animal waste**, crop residues, or grass clippings, is also encouraged as an alternative to chemical fertilizers. *See also* Cultural eutrophication; Recycling; Sustainable agriculture; Trace element/micronutrient

Fibrosis

A medical term that refers to the excessive growth of fibrous tissue in some part of the body. Many types of fibroses are known, including a number that affect the respiratory system. A number of these respiratory fibroses, including such conditions as **black lung disease**, silicosis, **asbestosis**, berylliosis, and byssinosis, are caused by environmental factors. A fibrosis develops when a person inhales very tiny solid particles or liquid droplets over many years or decades. Part of the body's reaction to these foreign particles is to enmesh them in fibrous tissue. The disease name usually suggests the agent that causes the disease. Silicosis, for example, is caused by the inhalation of silica, tiny sand-like particles. Occupational sources of silicosis include rock mining, quarrying, stone cutting, and sandblasting. Berylliosis is caused by the inhalation of beryllium particles over a period of time, and byssinosis (from byssos, the Greek word for flax)is found among textile workers who inhale flax, cotton or hemp fibers.

Field capacity

Field capacity refers to the amount of water that can be held in the **soil** after all the gravitational water has drained away. Sandy soils will have less water held at field capacity than clay soils. The more water a soil can hold at field capacity the more water is available for plants.

Filters

Primarily devices for removing particles from aerosols. Filters utilize a variety of microscopic forms and a variety of mechanisms to accomplish this. Most common are fibrous filters, in which the fibers are of cellulose (paper filters), but almost any fibrous material, including glass fiber, wool, **asbestos**, and finely spun polymers, has been used. Microscopically, these fibers collect fine particles because fine particles vibrate around their average position due to collision with air molecules (Brownian motion). These vibrations are likely to cause them to collide with the fibers as they pass through the filter. Larger particles are removed because, as the air stream carrying them passes through the filter, some of the particles are intercepted as they pass close to the fibers and touch them. Other particles are in air streams that would cause

them to miss the fibers, but when the air stream bends to go around the fibers the momentum, of the particles is too much to let them remain with the stream, so that they are "centrifuged out" onto the fibers (impaction). By electrophoresis, still other particles may be attracted to the fibers by electric charges of opposite sign on the particles and on the fibers. Finally, particles may simply be larger than the space between fibers, and be sifted out of the air in a process called sieving.

Filters are also formed by a process in which polymers such as cellulose esters are made into a film out of a solution in an organic solvent containing water. As the solvent evaporates, a point is reached at which the water separates out as microscopic droplets, in which the polymer is not soluble. The final result is a film of polymer full of microscopic holes where the water droplets once were. Such filters can have pore sizes from a small fraction of a micrometer to a few micrometers. (One micrometer equals 0.00004 in) These are called membrane filters.

Another form of membrane filter is formed from the polymer called polycarbonate. A thin film of this material is fastened to a surface of **uranium** metal and placed in a nuclear reactor for a time. In the reactor, the uranium undergoes **nuclear fission**, and gives off particles called fission fragments, atoms of the elements formed when the uranium atoms split. Every place that an atom from the fissioning uranium passes through the film is disturbed on a molecular scale. After removal from the reactor, if the polymer sheet is soaked in alkali, the disturbed material is dissolved. The amount of material dissolved is controlled by the temperature of the solution and the amount of time the film is treated. Since the fission fragments are very energetic, they travel in straight lines, and so the holes left after the alkali treatment are very straight and round. Again, pore sizes can be from a small fraction of a micrometer to a few micrometers. These filters are known by their trade name, *Nuclepore*.

In both types of membrane filters, the small pore size increases the role of sieving in particle removal. Because of their very simple structure, Nuclepore filters have been much studied to understand **filtration** mechanisms, since they are far easier to represent mathematically than a random arrangement of fibers.

It was mentioned above that small particles are collected because of their Brownian motion, while larger particles are removed by interception, impaction, and sieving. Under many conditions, a particle of intermediate size may pass through, too large for Brownian diffusion, and too small for impaction, interception, or sieving. Hence many filters may show a penetration maximum for particles of a few tenths of a micrometer. For this reason, standard methods of filter testing specify that the **aerosol** test for determining the efficiency of filters should contain particles in that size range. This phenomenon has also been used to select relatively uniform particles of that size out of mixtures of many sizes.

In circumstances where filter strength is of paramount importance, such as in industrial filters where a large air flow must pass through a relatively small filter area, filters of woven cloth are used, made of materials ranging from cotton to glass fiber and asbestos, these last for use when very hot gases must be filtered. The woven fabric itself is not a particularly good filter, but it retains enough particles to form a particle cake on the surface, and that soon becomes the filter. When the cake becomes thick enough to slow airflow to an unacceptable degree, the air flow is interrupted briefly, and the filters are shaken to dislodge the filter cake, which falls into bins at the bottom of the filters. Then filtration is resumed, allowing the cloth filters to be used for months before being replaced. A familiar domestic example is the bag of a home vacuum cleaner. Cement plants and some electric **power plants** use dozens of cloth bags up to several feet in diameter and more than ten feet (three meters) in length to remove particles from their waste gases.

Otherwise poor filters can be made efficient by making them thick. A glass tube can be partially plugged with a wad of cotton or glass fiber, then nearly filled with crystals of sugar or naphthalene and used as a filter; this is advantageous since sugar can be dissolved in water, or naphthalene will sublime away if gently heated, leaving behind the collected particles. *See also* Baghouse; Electrostatic precipitation; Odor control; Particulate

[*James P. Lodge Jr.*]

Filtration

A common technique for separating substances in two physical states. For example, a mixture of solid and liquid can be separated into its components by passing the mixture through a filter paper. Filtration has many environmental applications. In water purification systems, impure water is often passed through a charcoal filter to remove the solid and gaseous contaminants that give water a disagreeable odor, color, or taste. Trickling **filters** are used to remove solid wastes in plants. Solid and liquid contaminants in waste industrial gases can be removed by passing them through a filter prior to **discharge** in a smokestack.

Fire

see **Prescribed burning; Wildfire**

Fire ants

Two distinct **species** of fire ants (genus *Solenopsis*) from South America have been introduced into the United States this century. The South American black fire ant (*S. richteri*) was first introduced into the United States in 1918. Its close relative, the red fire ant (*S. wagneri*), was introduced in 1940, probably escaping from a South American freighter docked in Mobile, Alabama. Both species became established in the southeastern United States, spreading into nine states from Texas across to Florida and up into the Carolinas. It is estimated that they have infested over 320 million acres (130 million ha) covering 13 states as well as Puerto Rico.

Successful **introduced species** are often more aggressive than their native counterparts, and this is definitely true of fire ants. They are very small, averaging 0.2 in (5 mm) in length, but their aggressive, swarming behavior makes them a threat to livestock and pets as well as humans. These industrious, social insects build their nests in the ground—the location is easily detected by the elevated earthen mounds created from their excavations. The mounds are 18–36 in (46–91 cm) in diameter and may be up to 36 in (91 cm) high, although mounds are generally 6–10 in (15–25 cm) high. Each nest contains as many as 25,000 workers, and there may be over 100 nests on an acre of land.

If the nest is disturbed, fire ants swarm out of the mound by the thousands and attack with swift ferocity. As with other aspects of ant behavior, a chemical alarm pheromone is released that triggers the sudden onslaught. Each ant in the swarm uses its powerful jaws to bite and latch onto whatever disturbed the nest, while using the stinger on the tip of its abdomen to sting the victim repeatedly. The intruder may receive thousands of stings within a few seconds.

The toxin produced by the fire ant is extremely potent, and it immediately causes an intense burning pain that may continue for several minutes. After the pain subsides, the site of each sting develops a small bump which expands and becomes a tiny, fluid-filled blister. Each blister flattens out several hours later and fills with pus. These swollen pustules may persist for several days before they are absorbed and replaced by scar tissue. Fire ants obviously pose a problem for humans. Some people may become sensitized to fire ant venom, have a generalized systematic reaction, and go into anaphylactic shock. Fire-ant induced deaths have been reported. Because these species prefer open, grassy yards or fields, pets and livestock may fall prey to fire ant attacks as well.

Attempts to eradicate this **pest** involved the use of several different generalized pesticides, as well as the widespread use of **gasoline** either to burn the nest and its inhabitants or to kill the ants with strong toxic vapors. Another approach involved the use of specialized crystalline pesticides which were spread on or around the nest mound. The workers collected them and took them deep into the nest, where they were fed to the queen and other members of the colony, killing the inhabitants from within. A more recent method involves the release of a natural predator of the fire ant, the "phorid" fly. The fly releases an egg into the fire ant. The larva then eats the ant's brain while releasing an **enzyme**. The enzyme systematically destroys the joints causing the ant's head to fall off. The flies were released in 11 states as of 2001 and seem to be slowly inhibiting the growth of the fire ant population. As effective as some of these methods are, fire ants are probably too numerous and well established to be completely eradicated in North America.

First World

The world's more wealthy, politically powerful, and industrially developed countries are unofficially, but commonly, designated as the First World. The term differentiates the powerful, capitalist states of Western Europe and North America and Japan from the (formerly) communist states (**Second World**) and from the nonaligned, developing countries (**Third World**) in world systems theory. In common usage, First World refers mainly to a level of economic strength. The level of industrial development of the First World, characterized by an extensive infrastructure, mechanized production, efficient and fast transport networks, and pervasive use of high technology, consumes huge amounts of **natural resources** and requires an educated and skilled work force. However, such a system is usually highly profitable. Often depending upon raw materials imported from poorer countries (wood, metal ores, **petroleum**, food, and so on), First World countries efficiently produce goods that **less developed countries** desire but cannot produce themselves, including computers, airplanes, optical equipment,

and military hardware. Generally, high domestic and international demand for such specialized goods keeps First World countries wealthy, allowing them to maintain a high standard of material consumption, education, and health care for their citizens.

Fish and Wildlife Service

The United States Fish & Wildlife Service based in Washington, D.C., is charged with conserving, protecting, and enhancing fish, **wildlife**, and their habitats for the benefit of the American people. As a division of the **U.S. Department of the Interior**, the Service's primary responsibilities are for the protection of migratory birds, **endangered species**, freshwater and anadromous (saltwater **species** that spawn in freshwater rivers and streams) fisheries, and certain marine mammals.

In addition to its Washington, D.C., headquarters, the Service maintains seven regional offices and a number of field units. Those include national wildlife refuges, national fish hatcheries, research laboratories, and a nationwide network of law enforcement agents.

The Service manages 530 refuges that provide habitats for migratory birds, endangered species, and other wildlife. It sets migratory bird **hunting** regulations, and leads an effort to protect and restore endangered and threatened animals and plants in the United States and other countries.

Service scientists assess the effects of contaminants on wildlife and habitats. Its geographers and cartographers work with other scientists to map **wetlands** and carry out programs to slow wetland loss, or preserve and enhance these habitats. Restoring fisheries that have been depleted by **overfishing**, **pollution**, or other **habitat** damage is a major program of the Service. Efforts are underway to help four important species: lake trout in the upper **Great Lakes**; striped bass in both the **Chesapeake Bay** and Gulf Coast; Atlantic **salmon** in New England; and salmonid species of the Pacific Northwest.

Fish and Wildlife biologists working with scientists from other federal and state agencies, universities, and private organizations develop recovery plans for endangered and threatened species. Among its successes are the **American alligator**, no longer considered endangered in some areas, and a steadily increasing **bald eagle** population.

Internationally, the Service cooperates with 40 wildlife research and **wildlife management** programs, and provides technical assistance to many other countries. Its 200 special agents and inspectors help enforce wildlife laws and treaty obligations. They investigate cases ranging from individual migratory bird hunting violations to large-scale **poaching** and commercial trade in protected wildlife.

It its "Vision for the Future" statement, the Fish and Wildlife Service states its mission to "provide leadership to achieving a national net gain of fish and wildlife and the natural systems which support them." Into the twenty-first century, this vision statement calls for new **conservation** compacts with all citizens to increase the value of the United States wildlife holdings in number and **biodiversity**, and to provide increased opportunities for the public to use, associate with, learn about and enjoy America's wildlife wealth.

Fish farming

see **Blue revolution (fish farming)**

Fish kills

Fishing has long been a major provider of food and livelihood to people throughout the world. In the United States, 50 million people enjoy fishing as an outdoor recreation—38 million in fresh water and 12 million in salt water. Combined, they spend over $315 million annually on this sport. It is no surprise, then, that public attitude towards factors that influence fishing is strong.

The **Environmental Protection Agency** (EPA) is charged with overseeing the quality of the nation's waterways. In 1977 they received information on 503 separate incidents in which 16.5 million fish were killed. In 1974, a record 47 million fish were killed in the Black River near Essex, Maryland, by a **discharge** from a sewage plant.

Fish kills can result from natural as well as human causes. Natural causes include sudden changes in temperature, oxygen depletion, toxic gases, epidemics of viruses and bacteria, infestations of **parasites**, toxic algal blooms, lightning, **fungi**, and other similar factors. Human influences that lead to fish kills include **acid rain**, sewage **effluent**, and toxic spills.

In a 10-year study of the causes of 409 documented fish kills totaling 3.6 million fish in the state of Missouri,

S. M. Czarnezki determined the percentage contributions as: 26% municipal-related (sewage effluent), 17% from agricultural activities, 11% from industrial operations, 8% by **transportation** accidents, 7% each by oxygen depletions, nonindustrial operations, and mining, 4% by disease, 3% by "other" factors, and 10% as undetermined.

Fish kills may occur quite rapidly, even within minutes of a major toxic spill. Usually, however, the process takes days or even months, especially in natural causes. Experienced fishery biologists usually need a wide variety of physical, chemical, and biological tests of the **habitat** and fish to determine the exact causative agent or agents. The investigative procedure is often complex and may require a lot of time.

Species of fish vary in their susceptibility to the different factors that contribute to die-offs. Some species are sensitive to almost any disturbance, while other fish are tolerant of changes. As discussed below, predatory fish at the top of the **food chain/web** are typically the first fish affected by toxic substances that accumulate slowly in the water.

The most common contributor to fish kills by natural causes is oxygen depletion, which occurs when the amount of oxygen utilized by **respiration**, **decomposition**, and other processes exceeds oxygen input from the **atmosphere** and **photosynthesis**. Oxygen is more soluble in cold than warm water. Summer fish kills occur when lakes are thermally stratified. If the lake is eutrophic (highly productive), dead plant and animal matter that settles to the bottom undergoes decomposition, utilizing oxygen. Under windless conditions, more oxygen will be used than is gained, and animals like fish and **zooplankton** often die from suffocation.

Winter fish kills can also occur. Algae can photosynthesize even when the lake is covered with ice because sunlight can penetrate through the ice. However, if heavy snowfall accumulates on top of the ice, light may not reach the underlying water, and the **phytoplankton** die and sink to the bottom. **Decomposers** and respiring organisms again use up the remaining oxygen and the animals eventually die. When the ice melts in the spring, dead fish are found floating on the surface. This is a fairly common occurrence in many lakes in Michigan, Wisconsin, Minnesota, and surrounding states. For example, dead alewives (*Alosa pseudoharengus*) often wash up on the southwestern shore of Lake Michigan near Chicago during spring thaws following harsh winters.

In summer and winter, artificial **aeration** can help prevent fish kills. The addition of oxygen through aeration and mixing is one of the easiest and cheapest methods of dealing with low oxygen levels. In intensive **aquaculture** ponds, massive fish deaths from oxygen depletion are a constant threat. Oxygen sensors are often installed to detect low oxygen levels and trigger the release of pure oxygen gas from nearby cylinders.

Natural fish kills can also result from the release of toxic gases. In 1986, 1,700 villagers living on the shore of Lake Nyos, Cameroon, mysteriously died. A group of scientists sent to investigate determined that they died of asphyxiation. Evidently a **landslide** caused the trapped **carbon** dioxide-rich bottom waters to rapidly rise to the surface much like a popped champagne bottle. The poisonous gas killed everyone in its downwind path. Fish in the upper oxygenated waters of the lake were also killed as the **carbon dioxide** passed through.

Hydrogen sulfide (H_2S), a foul-smelling gas naturally produced in the oxygen-deficient sediments of eutrophic lakes, can also cause fish deaths. Even in oxygenated waters, high H_2S levels can cause a condition in fish called "brown blood." The brown color of the blood is caused by the formation of sulfhemoglobin, which inhibits the blood's oxygen-carrying capacity. Some fish survive, but sensitive fish such as trout usually die.

Fish kills can also result from toxic algal blooms. Some bluegreen algae in lakes and dinoflagellates in the ocean release **toxins** that can kill fish and other vertebrates, including humans. For example, dense blooms of bluegreen algae such as *Anabaena*, *Aphanizomenon*, and *Microcystis* have caused fish kills in many farm ponds during the summer. Fish die not only from the toxins but also from asphyxiation resulting from decomposition of the mass of algae that also die due to lack of sunlight in the densely-populated lake water. In marine waters, toxic dinoflagellate blooms called red tides are notorious for causing massive fish kills. For example, blooms of *Gymnodinium* or *Gonyaulax* periodically kill fish along the East and Gulf Coasts of the United States. Die-offs of **salmon** in aquaculture pens along the southwestern shoreline of Norway have been blamed on these organisms. Millions of dollars can be lost if the fish are not moved to clear waters. Saxitoxin, the toxic chemical produced by *Gonyaulax*, is 50 times more lethal than strychnine or curare.

Pathogens and parasites can also contribute to fish kills. Usually the effect is more secondary than direct. Fish weakened by parasites or infections of bacteria or viruses usually are unable to adapt to and survive changes in water temperature and chemistry. Under stressful conditions of over-crowding and malnourishment, gizzard shad often die from minor infestations of the normally harmless bacterium *Aeromonas hydrophila*. In the same way, fungal infections such as *Ichthyophonus hoferia* can contribute to fish kills. Most fresh water aquarium keepers are familiar with the threat of "ick" for their fish. The telltale white spots under the epithelium of the fins, body, and gills are caused by the protozoan parasite *Ichthyophthirius multifiliis*.

Changes in **pH** of lakes resulting from **acid** rain are a modern example of how humans can cause fish kills. **Atmospheric pollutants** such as **nitrogen** dioxide and **sulfur dioxide** released from automobiles and industries mix with water vapor and cause the rainwater to be more acid than normal (>pH 6.5). Nonprotected lakes downwind that receive this rainfall increase in acidity, and sensitive fish eventually die. Most of the once-productive trout streams and lakes in the southern half of Norway are now devoid of these prized fish. Sweden has combatted this problem by adding enormous quantities of lime to their affected lakes in the hope of neutralizing the acid's effects.

Sewage treatment plants add varying amounts of treated effluent to streams and lakes. Sometimes during heavy rainfall raw sewage escapes the treatment process and pollutes the aquatic **environment**. The greater the organic matter that comprises the effluent, the more decomposition occurs, resulting in oxygen usage. Scientists call this the biological or **biochemical oxygen demand** (BOD), the quantity of oxygen required by bacteria to oxidize the **organic waste** aerobically to carbon dioxide and water. It is measured by placing a sample of the **wastewater** in a glass-stoppered bottle for five days at 71 degrees Fahrenheit (20 degrees Celsius) and determining the amount of oxygen consumed during this time. Domestic sewage typically has a BOD of about 200 milligrams per liter, or 200 **parts per million** (ppm); rates for industrial waste may reach several thousand milligrams per liter. Reports of fish kills in industrialized countries have greatly increased in recent years. Sewage effluent not only kills fish; it can also create a barrier to fish migrating upstream because of the low oxygen levels. For example, coho salmon will not pass through water with oxygen levels below 5 ppm. Oxygen depletion is often more detrimental to fish than thermal shock.

Toxic **chemical spills**, whether via sewage treatment plants or other sources, are the major cause of fish kills. Sudden discharges of large quantities of highly toxic substances usually cause massive death of most aquatic life. If they enter the **ecosystem** at sublethal levels over a long time, the effects are more subtle. Large predatory or omnivorous fish are typically the first ones affected. This is because toxic **chemicals** like methyl **mercury**, DDT, PCBs, and other organic pollutants have an affinity for fatty tissue and progressively accumulate in organisms up the food chain. This is called the principle of **biomagnification**. Unfortunately for human consumers, these fish do not usually die right away, so people who eat a lot of tainted fish become sick and possibly die. Such is the case for **Minamata disease**, named for the first documented connection between the death of fishermen and methyl mercury contamination.

Fisheries and Oceans Canada

The Department of Fisheries and Oceans (DFO) in Canada was created by the Department of Fisheries and Oceans Act on April 2, 1979. This act formed a separate government department from the Fisheries and Marine Service of the former Department of Fisheries and the Environment. The new department was needed, in part, because of increased interest in the management of Canada's oceanic resources, and also because of the mandate resulting from the unilateral declaration of the 200-nautical-mi Exclusive Economic Zones in 1977.

At its inception, the DFO assumed responsibility for seacoast and inland fisheries, fishing and recreational vessel harbors, hydrography and ocean science, and the coordination of policy and programs for Canada's oceans. Four main organizational units were created: Atlantic Fisheries, Pacific and Freshwater Fisheries, Economic Development and Marketing, and Ocean and Aquatic Science. Among the activities included in the department's original mandate were: comprehensive husbandry of fish stocks and protection of **habitat**; "best use" of fish stocks for optimal socioeconomic benefits; adequate hydrographic surveys; the acquisition of sufficient knowledge for defense, **transportation**, energy development and fisheries, with provision of such information to users; and continued development and maintenance of a national system of harbors.

Since its inception, the department's mandate has changed in minor ways, to include new terminology such as "sustainability" and to include Canada's "ecological inter-

ests." Recently, attention has been given to support those who make their living or benefit from the sea. This constituency includes the public first, but the DFO also directs its efforts toward commercial fishers, fish plant workers, importers, aquaculturists, recreational fishers, native fishers, and the ocean manufacturing and service sectors. There are now six DFO divisions: Science, Atlantic Fisheries, Pacific Fisheries, Inspection Services, International, and Corporate Policy and Support administered through six regional offices.

A primary focus of DFO's current work is the failing cod and groundfish stocks in the Atlantic; the department has commissioned two major inquiries in recent years to investigate those problems. In addition, the DFO has increased regulation of foreign fleets, and works to manage straddling stocks in the Atlantic **Exclusive Economic Zone** through the North Atlantic Fisheries Organization, the Pacific drift nets fisheries, recreational fishing and **aquaculture** development. In 1992, management problems in the major fisheries arose on both the Pacific and Atlantic coasts. American fisheries managers reneged on quotas established through the Pacific **Salmon** Treaty, northern cod stocks in Newfoundland virtually failed, and the Aboriginal Fishing Strategy was adopted as part of a land claim settlement on the Pacific coast.

There are several major problems associated with ocean resource and environment management in Canada—problems that the DFO has neither the resources, the legislative infrastructure, nor the political will to address. One result of this has been the steady decline of commercial fish stocks, highlighted by the virtual collapse of Atlantic cod (*Gadus callarias*), which is Canada's, and perhaps, the Atlantic's most historically significant fishery. A second result has been an increased need to secure international agreements with Canada's ocean neighbors. A third result of social significance is the perception that fisheries have been used in a political sense in cases of regional economic incentives and land claims settlements. *See also* Commercial fishing; Department of Fisheries and Oceans (DFO), Canada

Floatable debris

Floatable debris is buoyant **solid waste** that pollutes waterways. Sources include boats and shipping vessels, storm water **discharge**, sewer systems, industrial activities, offshore drilling, recreational beaches, and landfills. Even waste dumped far from a water source can end up as floatable debris when **flooding**, high winds, or other weather conditions transport it into rivers and streams.

According to the U.S. **Environmental Protection Agency** (EPA), floatable debris is responsible for the death of over 100,000 marine mammals and one million seabirds annually. **Seals**, **sea lions**, **manatees**, **sea turtles**, and other marine creatures often mistake debris for food, eating objects that block their intestinal tract or cause internal injury. They can also become entangled in lost fishing nets and line, six-pack rings, or other objects.

Fishing nets lost at sea catch tons of fish that simply decompose, a phenomenon known as "ghost fishing." Often, seabirds are ensnared in these nets when they try to eat the fish.

Lost nets and other entrapping debris are also a danger for humans who swim, snorkel, or scuba dive. And biomedical waste and sewage can spread disease in recreational waters. Floatable debris takes a significant financial toll as well. It damages boats, deters tourism, and negatively impacts the fishing industry.

Flooding in Texas caused by Hurricane Beulah in 1967. (National Oceanic and Atmospheric Administration.)

Flooding

Technically, flooding occurs when the water level in any stream, river, bay, or lake rises above bank full. Bays may flood as the result of a tsunami or tidal wave induced by an **earthquake** or volcanic eruption; or as a result of a tidal storm surge caused by a **hurricane** or tropical storm moving inland. Streams, rivers and lakes may be flooded by high amounts of surface **runoff** resulting from widespread precipitation or rapid snow melt. On a smaller scale, flash floods due to extremely heavy precipitation occurring over a short period of time can flood streams, creeks, and low lying areas in a matter of a few hours. Thus, there are various temporal and spatial scales of flooding. Historical evidence suggests that flooding causes greater loss of life and property than any other natural disaster. The magnitude, seasonality, frequency, velocity, and load are all properties of flooding which are studied by meteorologists, climatologists, and hydrologists.

Spring and winter floods occur with some frequency primarily in the mid-latitude regions of the earth, and particularly where continental **climate** is the norm. Five climatic features contribute to the spring and winter flooding potential of any individual year or region: 1) heavy winter snow cover; 2) saturated soils or soils at least near their **field capacity** for storing water; 3) rapid melting of the winter's snow pack; 4) frozen **soil** conditions which limit **infiltration**; and 5) somewhat heavy rains, usually from large scale cyclonic storms. Any combination of three of these five climatic features usually leads to some type of flooding. This type of flooding can cause hundreds of millions of dollars in property damage, but it can usually be predicted well in advance, allowing for evacuation and other protective action to be taken (sandbagging, for instance). In some situations flood control measures such as stream or channel diversions, **dams**, and levees can greatly reduce the risk of flooding. This is more often done in **floodplain** areas with histories of very damaging floods. In addition, **land use** regulations, encroachment statutes and building codes are often intended to protect the public from the risk of flooding.

Flash flooding is generally caused by violent weather, such as severe thunderstorms and hurricanes. This type of flooding more frequently occurs during the warm season when convective thunderstorms develop more frequently.

Rainfall intensity is so great that the **carrying capacity** of streams and channels is rapidly exceeded, usually within hours, resulting in sometimes life-threatening flooding. It is estimated that the average death toll in the United States exceeds 200 per year as a result of flash flooding. Many government weather services provide the public with flash flood watches and warnings to prevent loss of life. Many flash floods occur as the result of afternoon and evening thundershowers which produce rainfall intensities ranging from a few tenths of an inch per hour to several inches per hour. In some highly developed urban areas, the risk of flash flooding has increased over time as the native vegetation and soils have been replaced by buildings and pavement which produce much higher amounts of surface runoff. In addition, the increased usage of parks and recreational facilities which lie along stream and river channels has exposed the public to greater risk. *See also* Urban runoff

Floodplain

An area that has been built up by stream deposition, generally represented by the main **drainage** channel of a **watershed**, is called a floodplain. This area, usually relatively flat with respect to the surrounding landscape, is subject to periodic **flooding**, with

return periods ranging from one year to 100 years. Floodplains vary widely in size, depending on the area of the drainage basin with which they are associated. The soils in floodplains are often dark and fertile, representing material lost the to erosive forces of heavy precipitation and **runoff**. These soils are often farmed, though subject to the risk of periodic crop losses due to flooding. In some areas, floodplains are protected by flood control measures such as reservoirs and levees and are used for farming or residential development. In other areas, land-use regulations, encroachment statutes and local building codes often prevent development on floodplains.

Flora

All forms of plant life that live in a particular geographic region at a particular time in history. A number of factors determine the flora in any particular area, including temperature, sunlight, **soil**, water, and evolutionary history. The flora in any given area is a major factor in determining the type of **fauna** found in the area. Scientists have divided the earth's surface into a number of regions inhabited by distinct flora. Among these regions are the African-Indian **desert**, western African **rain forest**, Pacific North American region, Arctic and Sub-arctic region, and the Amazon.

Florida panther

The Florida panther (*Felis concolor coryi*), a subspecies of the mountain lion, is a member of the cat family, Felidae, and is severely threatened with **extinction**. Listed as endangered, the Florida panther population currently numbers between 30 and 50 individuals. Its former range probably extended from western Louisiana and Arkansas eastward through Mississippi, Alabama, Georgia, and southwestern South Carolina to the southern tip of Florida. Today the Florida panther's range consists of the Everglades-Big Cypress Swamp area. The preferred **habitat** for this large cat is subtropical forests comprised of dense stands of trees, vines, and shrubs, typically in low, swampy areas.

Several factors have contributed to the decline of the Florida panther. Historically the most significant factors have been habitat loss and persecution by humans. **Land use** patterns have altered the **environment** throughout the former range of the Florida panther.

With shifts to cattle ranching and agriculture, lands were drained and developed, and with the altered vegetation patterns came a change in the prey base for this top carnivore. The main prey item of the Florida panther is white-tailed deer (*Odocoileus virginianus*). Formerly, the spring and summer rains kept the area wet, and then, as it dried out, fires would renew the grassy meadows at the forest edges, creating an ideal habitat for the deer. With development and increased deer **hunting** by humans, the panther's prey base declined and so did the number of panthers. Prior to the 1950s, Florida had a bounty on Florida panthers because the animal was considered a "threat" to humans and livestock. During the 1950s, state law protected the dwindling population of panthers. In 1967 the Florida panther was listed by the U. S. **Fish and Wildlife Service** as an **endangered species**.

Land development is still moving southward in Florida. With the annual influx of new residents, fruit orchards being moved south due to recent freezes, and continued draining and clearing of land, panther habitat continues to be destroyed. The Florida panther is forced into areas that are not good habitat for white-tailed deer, and the panthers are catching armadillos and raccoons for food. The panthers then become underweight and anemic due to poor nutrition.

A Florida panther (*Felis concolor coryi*). (Photograph by Tom and Pat Leeson. Photo Researchers Inc. Reproduced by permission.)

Development contributes to the Florida panther's decline in other ways, too. Its range is currently split in half by the east-west highway known as Alligator Alley. During peak seasons, over 30,000 vehicles traverse this stretch of highway daily, and, since 1972, 44 panthers have been killed by cars, the largest single cause of death for these cats in recent decades.

Biology is also working against the Florida panther. Because of the extremely small population size, **inbreeding** of panthers has yielded increased reproductive failures, due to deformed or infertile sperm. The spread of feline distemper **virus** also is a concern to **wildlife** biologists. All these factors have led officials to develop a recovery plan that includes a captive breeding program using a small number of injured animals, as well as a mark and recapture program, using radio collars, to **inoculate** against disease and track young panthers with hopes of saving this valuable part of the biota of south Florida's **Everglades ecosystem**.

Flotation

An operation in which submerged materials are floated, by means of air bubbles, to the surface of a water and removed. Bubbles are generated through a system called dissolved air flotation (DAF), which is capable of producing clouds of very fine, very small bubbles. A large number of small-sized bubbles is generally most efficient for removing material from water.

This process is commonly used in **wastewater** treatment and by industries, but not in **water treatment**. For example, the mining industry uses flotation to concentrate fine ore particles, and flotation has been used to concentrate **uranium** from sea water. It is commonly used to thicken the sludges and to remove grease and oil at wastewater treatment plants. The textile industry often uses flotation to treat process waters resulting from dyeing operations. Flotation might also be used to remove surfactants. Materials that are denser than water or that dissolve well in water are poor candidates for flotation. Flotation should not be confused with foam separation, a process in which surfactants are added to create a foam that affects the removal or concentration of some other material.

Flu pandemic

The influenza outbreak of 1918–1919 carried off between 20 to 40 million people worldwide. The Spanish flu outbreak differed significantly from other influenza (flu) epidemics. It was much more lethal, and it killed a high proportion of otherwise healthy adults. Most flu outbreaks kill only the very young, the elderly, and people with weakened immune systems. Scientists and public health officials have been trying to learn more about Spanish flu in the hopes of preventing a similar outbreak.

The Spanish flu **virus** caused one of the worst pandemic of an infectious disease ever recorded. And while the threat of many infectious diseases, including tuberculosis and smallpox, have been contained by antibiotics and vaccination programs, influenza remains a difficult disease. There are worldwide outbreaks of influenza every year, and the flu typically reaches pandemic proportions (lethally afflicting an

unusually high portion of the population) every 10–40 years. The last influenza pandemic was the Hong Kong flu of 1968–69, which caused 700,000 deaths worldwide, and killed 33,000 Americans. The influenza virus is highly mutable, so each year's flu outbreak presents the human body with a slightly different virus. Because of this, people do not build an immunity to influenza. Vaccines are successful in protecting people against influenza, but vaccine manufacturers must prepare a new batch each year, based on their best supposition of which particular virus will spread. Most influenza viruses originate in China, and doctors, scientists, and public health officials closely monitor flu cases there in order to make the appropriate vaccine. The two main organizations tracking influenza are the Centers for Disease Control (CDC) and the World Health Organization (WHO). The CDC and other government agencies have been preparing for a flu pandemic on the level of Spanish flu since the early 1990s.

Spanish flu did not originate in Spain, but presumably in Kansas, where the first case was recorded in March, 1918, at the army base Camp Funston. It quickly spread across the United States, and then to Europe with American soldiers who were fighting in the last months of World War I. Infected ships brought the outbreak to India, New Zealand, and Alaska. Spanish flu killed quickly. People often died within 48 hours of first feeling symptoms. The disease afflicted the lungs, and caused the tiny air sacs, called alveoli, to fill with fluid. Victims were soon starved of oxygen, and sometimes effectively drowned on the fluid clogging their lungs. Children and old people recovered from the Spanish flu at a much higher rate than young adults. In the United States, the death rate from Spanish flu was several times higher for men aged 25–29 than for men in their seventies.

Social conditions at the time probably contributed to the remarkable power of the disease. The flu struck just at the end of World War I, when thousands of soldiers were moving from America to Europe and across that continent. In a peaceful time, sick people may have gone home to bed, and thus passed the disease only to their immediate family. But in 1918, men with the virus were packed in already crowded hospitals and troop ships. The unrest and devastation left by the war probably hastened the spread of Spanish flu. So it is possible that if a similarly virulent virus were to arise again soon, it would not be quite as destructive.

Researchers are concerned about a return of Spanish flu because little is known about what made it so virulent. The flu virus was not isolated until 1933, and since then, there have been several efforts to collect and study the 1918 virus by exhuming graves in Alaska and Norway, where bodies were preserved in permanently frozen ground. In 1997, a Canadian researcher, Kirsty Duncan, was able to extract tissue samples from the corpses of seven miners who had died of Spanish flu in October 1918 and were buried in frozen ground on a tiny island off Norway. Duncan's work allowed scientists at several laboratories around the world to do genetic work on the Spanish flu virus. But by 2002, there was still no conclusive agreement on what was so different about the 1918 virus.

The influenza virus is believed to originate in migratory water fowl, particularly ducks. Ducks carry influenza viruses without becoming ill. They excrete the virus in their feces. When their feces collect in water, other animals can become infected. Domestic turkeys and chickens can easily become infected with influenza virus borne by wild ducks. But most avian (bird-borne) influenza does not pass to humans, or if it does, is not particularly virulent. But other mammals too can pick up influenza from either wild birds or domestic fowl. **Whales**, **seals**, ferrets, horses, and pigs are all susceptible to bird-borne viruses. When the virus moves between **species**, it may mutate. Human influenza viruses most likely pass from ducks to pigs to humans. The 1918 virus may have been a particularly unusual combination of avian and swine virus, to which humans were unusually vulnerable.

Enacting controls on pig and poultry farms may be an important way to prevent the rise of a new influenza pandemic. Some influenza researchers recommend that pigs and domestic ducks and chickens not be raised together. Separating pigs and fowl at live markets may also be a sensible precaution. With the concentration of poultry and pigs at huge "factory" farms, it is important for farmers, veterinarians, and public health officials to monitor for influenza. A flu outbreak among chickens in Hong Kong in 1997 eventually killed six people, but the epidemic was stopped by the quick slaughter of millions of chickens in the area. Any action to control flu of course must be an international effort, since the virus moves rapidly without respect to national borders.

Flue gas

The exhaust gas vented from **combustion**, a chemical reaction, or other physical process, which passes through a duct into the **atmosphere**. Exhaust air is usually captured by an enclosure and brought into the exhaust duct through induced or forced ventilation. Induced ventilation is created by lowering the pressure in the duct using fans at the end of the duct. Forced ventilation occurs when exhaust air is forced into the duct using high pressure inlet air. Flues are valuable because they not only direct polluted air to a **pollution control** device, but also keep the air pollutant concentrations high. High concentrations can be important if the air pollutant removal process is concentration dependent. *See also* Air pollution control

Flue-gas scrubbing

Flue-gas scrubbing is a process for removing oxides of sulfur and **nitrogen** from the waste gases emitted by various industrial processes. Since the oxides of sulfur and nitrogen have been implicated in a number of health and environmental problems, controlling them is an important issue. The basic principle of scrubbing is that flue gases are forced through a system of baffles within a smokestack. The baffles contain some chemical or **chemicals** that remove pollutants from these gases.

A number of scrubbing processes are available, all of which depend on the reaction between the oxide and some other chemical to produce a harmless compound that can then be removed from the smokestack. For example, currently the most common scrubbing reaction involves the reaction between **sulfur dioxide** and lime. In the first step of this process, limestone is heated to produce lime. The lime then reacts with sulfur dioxide in flue gases to form calcium sulfite, which can be removed with **electrostatic precipitation**.

Many other scrubbing reactions have been investigated. For example, magnesium oxide can be used in place of calcium oxide in the scrubber. The advantage of this reaction is that the magnesium sulfite that is formed decomposes readily when heated. The magnesium oxide that is regenerated can then be reused in the scrubber while the sulfur dioxide can be used to make sulfuric **acid**. In yet another process, a mixture of sodium citrate and citric acid is used in the scrubber. When sulfur dioxide is absorbed by the mixture, a reaction occurs in which elemental sulfur is precipitated out.

Although the limestone/lime process is by far the most popular scrubbing reaction, it has one serious disadvantage. The end product, calcium sulfite, is a solid that must be disposed of in some way. **Solid waste** disposal is already a serious problem in many areas, so adding to that problem is not desirable. For that reason, reactions such as those involving magnesium oxide, sodium citrate and citric acid have been carefully studied. The products of these reactions, sulfuric acid and elemental sulfur, are valuable raw materials that can be sold and used. In spite of that fact, the limestone/lime scrubbing process, or some variation of it, remains the most popular method of extracting sulfur dioxide from flue gases today.

Scrubbing to remove **nitrogen oxides** is much less effective. In principle, reactions like those used with sulfur dioxide are possible. For example, experiments have been conducted in which ammonia or **ozone** is used in the scrubber to react with and remove oxides of nitrogen. But such methods have had relatively little success and are rarely used by industry.

Flue gas scrubbing has long met with **resistance** from utilities and industries. For one thing, they are not convinced that oxides of sulfur and nitrogen are as dangerous as environmentalists sometimes claim. In addition, they argue that the cost of installing **scrubbers** is often too great to justify their use. *See also* Air pollution control; Dry alkali injection; Stack emissions

Fluidized bed combustion

Of all **fossil fuels**, **coal** exists in the largest amount. In fact, the world's coal resources appear to be sufficient to meet our energy needs for many hundreds of years. One aim of energy technology, therefore, is to find more efficient ways to make use of these coal reserves. One efficiency procedure that has been under investigation for at least two decades is known as fluidized bed **combustion**.

Fluidized bed combustion. Fuel is lifted by a stream of air from underneath the bed. Fuel efficiency is good and sulfur dioxide and nitrogen oxide emissions are lower than with conventional boilers. (McGraw-Hill Inc. Reproduced by permission.)

In a fluidized bed boiler, granulated coal and limestone are fed simultaneously onto a moving grate. A stream of air from below the grate lifts coal particles so that they are actually suspended in air when they begin to burn. The flow of air, small size of the coal particles, and exposure of the particles on all sides contribute to an increased rate of combustion. Heat produced by burning the coal is then used to boil water, run a turbine, and drive a generator, as in a conventional power plant.

The fluidized bed process has much to recommend it from an environmental standpoint. Sulfur and **nitrogen oxides** react with limestone added to the boiler along with the coal. The product of this reaction, primarily calcium sulfite and calcium sulfate, can be removed from the bottom of the boiler. However, disposing of large quantities of this waste product represents one of the drawbacks of the fluidized bed system.

Fly ash is also reduced in the fluidized bed process. As coal burns in the boiler, particles of fly ash tend to adhere to each other, forming larger particles that eventually settle out at the bottom of the boiler. Conventional methods of removal in the stack, such as **electrostatic precipitation**, can further increase efficiency with which particles are removed.

Incomplete combustion of coal is common in the fluidized bed process. However, **carbon monoxide** and **hydrogen** sulfide formed in this way are further oxidized in the space above the moving grate. The products of this further oxidation are then removed by the limestone (which reacts with **sulfur dioxide**) or allowed to escape harmlessly in to the air (in the case of the **carbon dioxide**). After being used as a **scavenger** in the process, the limestone, calcium sulfite, and calcium sulfate can be treated to release sulfur dioxide and regenerate the original limestone. The limestone can then be re-used and the sulfur dioxide employed to make sulfuric **acid**.

A further advantage of the fluidized bed process is that it operates at a lower temperature than does a conventional power plant. Thus, the temperature of cooling water ejected from the plant is lower, and the amount of **thermal pollution** of nearby waterways correspondingly lessened.

Writers in the 1970s expressed high hopes for the future of fluidized bed combustion systems, but the cost of such systems is still at least double that of a conventional plant. They are also only marginally more efficient than a conventional plant. Still, their environmental assets are obvious. They should reduce the amount of sulfur dioxide emitted by up to 90% and the amount of **nitrogen** oxides by more than 60%. *See also* Air pollution control; Stack emissions

Fluoridation

Fluoridation is the precise adjustment of the concentration of the essential trace element fluoride in the public water supply to protect teeth and bones. Advocates of fluoridation such as the American Dental Association (ADA) and the National Center for Chronic Disease Prevention and Health Promotion (CDC) state that fluoridation is a safe and effective method of preventing tooth decay. Opponents of fluori-

dation however, such as Citizens for Health and the Fluoride Action Metwork, maintain that the role fluoridation in the decline of tooth decay is in serious doubt and that more research is required before placing a compound in water reservoirs that could cause **cancer**, brittle bones, and neurological problems.

Fluoride is any compound that contains fluorine, a corrosive, greenish-yellow element. Tooth enamel contains small amounts of fluoride. In addition, fluoride is found in varying amounts in water and in all food and beverages, according to the ADA.

A Colorado dentist discovered the effects of fluoride on teeth in the 1900s. When Frederick McKay began practicing in Colorado Springs, he established a connection between a substance in the water and the condition of residents' teeth. People did not have cavities, but their teeth were stained brown. Dental research started on the substance that was identified as fluoride during the 1930s. Researchers concluded that a concentration of fluoride in drinking water at a ratio of 1 part per million (ppm) prevented tooth decay without staining teeth. In 2000, the ADA stated that a fluoride concentration ranging from 0.7 ppm to 1.2 ppm was sufficient to fight tooth decay.

The first community to try fluoridation was Grand Rapids, Michigan. The city fluoridated the community water supply in 1945. Ten years later, Grand Rapids reported that incidents of tooth decay had declined by 60% in the children raised on fluoridated water. During the 1950s, Chicago, Philadelphia, and San Francisco also started to fluoridate their water supply. Cities including New York and Detroit opted for fluoridation during the 1960s. However, not all Americans advocated fluoridation. During the 1950s and 1960s, members of the John Birch Society maintained that fluoridation was a form of mass medication by the government. Some members charged that fluoridation was part of a Communist plot to take over the country. In the decades that followed, fluoridation was no longer associated with conspiracy theories. However, opinion about fluoridation was divided at the close of the twentieth century. By 2000, public water systems served 246.1 million Americans, according to the federal CDC. Of that amount, 65.8% of Americans used fluoridated water.

In Washington D.C., 100% of the water is fluoridated, according to a CDC report on the percentage of state populations with fluoridated public water systems in 2000. The top 10 on the list were: Minnesota (98.2%), Kentucky (96.1%), North Dakota (95.4%), Indiana (95.3%), Tennessee (94.5%), Illinois (93.4%), Virginia (93.4%), Georgia (92.9%), Iowa (91.3%), and South Carolina (91.2%). At the other end of the spectrum in terms of fluoridated public water usage were: Louisiana (53.2%), Mississippi (46%), Idaho (45.4%), New Hampshire (43%), Wyoming (30.3%), California (28.7%), Oregon (22.7%), Montana (22.2%), New Jersey (15.5%), Hawaii (9%), and Utah (2%). The CDC estimated the cost of fluoridation at 50 cents per year in communities of more than 20,000 residents. The annual cost was estimated at $1 in communities of 10,000 to 20,000 residents. In communities numbering less than 5,000 people, the yearly cost was estimated at $3.

The CDC reported in 2000 that extensive research during the previous 50 years proved that fluoridation was safe. Fluoridation was also endorsed by groups including the American Medical Association, the American Academy of Pediatrics, the National PTA, and the American Cancer Society. Advocates of fluoridation state that it especially benefits people who may not be able to afford dental care. Opponents however, counter that toothpaste with fluoride is available for people who believe that fluoride fights tooth decay. Furthermore, opponents point out that toothpaste with fluoride contains a warning label advising users to "seek professional assistance or contact a poison control center" if they accidentally swallow more than the amount used for brushing teeth. Lastly, their question the research methodology used to conclude that fluoridation is responsible for decreased tooth decay. Fluoridation critics include consumer advocates **Ralph Nader** and Jim Turner. Turner chairs the board of Citizens for Health, a grassroots organization that is asking Congress to hold hearings and review fluoridation policy. Citizens for Health belongs to the groups that believe more research is required to determine the risks and benefits of fluoridation.

Fly ash

The fine ash from **combustion** processes that becomes dispersed in the air. To the casual observer it might appear as **smoke**, and indeed it is often found mixed with smoke. Fly ash arises because fuels contain a small fraction of incombustible matter. In a fuel like **coal**, ash has a rock-like siliceous composition, but the high temperatures at which it is formed often means that metals such as iron are incorporated into the ash particles, which take on the appearance of small, colored, glassy spheres. **Petroleum** produces less ash, but it is often associated with a range of oxides such as vanadium (in the case of fuel oils) and, more noticeably, hollow spheres of **carbon**. In traditional furnaces, much ash remained on the grate, but modern furnaces produce such fine ash that it is carried away in the hot exhaust gas.

Early power stations dispersed so much fine fly ash throughout the nearby **environment** that they were soon forced to adopt early **pollution** abatement techniques. They adopted "cyclones" in which centrifugal force removes the particles by causing the waste gas stream to flow on a curved or vortical course. This technique is effective down to particle sizes of about 10 μm, but smaller particles are not removed well by **cyclone** collectors and here **electrostatic precipitation** process often proves more successful, coping with a size range 30—0.1 μm. In electrostatic precipitators the particles are given a negative charge and then attracted to a positive electrode where they are collected and removed. Cloth or paper **filters** and spraying water through the exhaust gases can be useful in removing fly ash.

Fly ash is a nuisance at high concentrations because it accumulates as grit on the surfaces of buildings, clothes, cars, and outdoor furnishings. It is a highly visible and very annoying aspect of industrial **air pollution**. The deposition of fly ash increases cleaning costs incurred by people who live near poorly controlled combustion sources. Fly ash also has health impacts because the finer particles can penetrate into the human lung. If the deposits are especially heavy, fly ash can also inhibit plant growth.

Each year millions of tons of fly ash are produced from coal-powered furnaces, most of which are dumped in waste tips. Care needs to be taken that toxic metals and alkalis are not leached from these disposal sites into watercourses. Fly ash may be used as a low grade cement in road building because it contains a large amount of calcium oxide but generally, the demand is rather low.

Flyway

The route taken by migratory birds and waterfowl when they travel between their breeding grounds and their winter homes. Flyways often follow geographic features such as mountain ranges, rivers, or other bodies of water. Protecting flyways is one of the many responsibilities of **wildlife** managers. Draining of **wetlands**, residential and commercial development, and **overhunting** are some of the factors that threaten flyway sites visited by birds for food and rest during **migration**. In most cases, international agreements are needed to guarantee protection along the entire length of a flyway. In the United States, flyway protection is financed to a large extent by funds produced through the Migratory Bird **Hunting** Stamp Act passed by the U.S. Congress in 1934.

Food additives

Food additives are substances added to food as flavorants, nutrients, preservatives, emulsifiers, or colorants. In addition, foods may contain residues of **chemicals** used during the production of plant or animal crops, including pesticides, antibiotics, and growth hormones. The use of most food additives is clearly beneficial because it results in improved public health and prevention of spoilage, which enhances the food supply. Nevertheless, there is controversy about the use of many common additives and over the presence of contaminants in food. This is partly because some people are hypersensitive and suffer allergic reactions if they are exposed to certain of these chemicals. In addition, some people believe that low levels of chronic toxicity and diseases may be caused in the larger population by exposure to some of these substances. Although there is no compelling scientific evidence that this is indeed the case, the possibility of chronic damage caused by food additives and chemical residues is an important social and scientific issue.

The use of food additives in the United States is closely regulated by the government agencies responsible for health, consumer safety, and agriculture. This is also the case of other developed countries in Europe, Canada, and elsewhere. Chemicals cannot be used as additives in those countries unless regulators are convinced that they have been demonstrated to be toxicologically safe, with a wide margin of security. In addition, chemicals added to commercially prepared foods must be listed on the packaging so that consumers can know what is present in the foodstuffs that they choose to eat. Because of the intrinsic nature of low-level, toxicological risks, especially those associated with diseases that may take a long time to develop, scientists are never able to demonstrate that trace exposures to any chemical are absolutely safe—there is always a level of risk, however small.

UNHEALTHY FOOD ADDITIVES		
Name	***Description***	***Example products***
Aspartame	An artificial sweetener associated with rashes, headaches, dizziness, depression, etc.	Diet sodas, sugar substitutes, etc.
Brominated vegetable oil (BVO)	Used as an emulsifier and clouding agent. Its main ingredient, bromate, is a poison.	Sodas, etc.
Butylated hydroxyanisole (BHA)/ butylated hydroxytoluene (BHT)	Prevents rancidity in foods and is added to food packagings. It slows the transfer of nerve impulses and affects sleep, aggressiveness, and weight in test animals.	Cereal and cheese packaging
Citrus red dye #2	Used to color oranges, it is a probable carcinogen. The FDA has recommended it be banned.	Oranges
Monosodium gltamate (MSG)	A flavor enhancer that can cause headaches, heart palpitations, and nausea.	Fast food, processed and packaged food
Nitrites	Used as preservatives, nitrites form cancer-causing compounds in the gastrointestinal tract and have been associated with cancer and birth defects.	Cured meats and wine
Saccharin	An artificial sweetener that may be carcinogenic.	Diet sodas and sugar substitutes
Sulfites	Used as a food preservative, sulfites have been linked to at least four deaths reported to the FDA in the United States.	Dried fruits, shrimp, and frozen potatoes
Tertiary butyhydroquinone (TBHQ)	It is extremely toxic in low doses and has been linked to childhood behavioral problems.	Candy bars, baking sprays, and fast foods
Yellow dye #6	Increases the number of kidney and adrenal gland tumors in lab rats. It has been banned in Norway and Sweden.	Candy and sodas

Because some people object to these potential, low-level, often involuntary risks, a certain degree of controversy will always be associated with the use of food additives. This is also true of the closely related topic of residues of pesticides, antibiotics, and growth hormones in foods.

Flavorants

Certain chemicals are added to foods to enhance their flavor. This is particularly true of commercially processed or prepared foods, such as canned vegetables and frozen foods and meals. One of the most commonly added flavorants is table salt (or sodium chloride), a critical **nutrient** for humans and other animals. In large amounts, however, sodium chloride can predispose people to developing high blood pressure, a factor that is important in strokes and other circulatory and heart diseases.

Table sugar (or sucrose), manufactured from sugar cane or sugar beets, and fructose, or fruit sugar, are commonly used to sweeten prepared foods. Such foods include sugar candies, chocolate products, artificial drinks, sweetened fruit juices, peanut butter, jams, ketchup, and most commercial breads. Sugars are easily assimilated from foods and are a useful form of metabolic energy. In large amounts, however, sugars can lead to weight gain, tooth decay, and hypoglycemia and diabetes in genetically predisposed people. Artificial sweeteners such as saccharine, aspartame, and sodium cyclamate avoid the nutritional problems associated with eating too much sugar. These nonsugar sweeteners may have their own problems, however, and some people consider them to be a low-level health hazard.

Monosodium glutamate (or MSG) is commonly used as a flavor enhancer, particularly in processed meats, prepared soups, and oriental foods. Some people are relatively sensitive to this chemical, developing headaches and other symptoms that are sometimes referred to as "Chinese food syndrome." Other flavorants used in processed foods include many kinds of spices, herbs, vanilla, mustard, nuts, peanuts, and wine. Some people are extremely allergic to even minute exposures to peanuts or nuts in food and can rapidly develop a condition known as anaphylactic shock, which is life-threatening unless quickly treated with medicine. This is one of the reasons why any foods containing peanuts or nuts as a flavoring ingredient must be clearly labeled as such.

Many flavorants are natural in origin. Increasingly, however, synthetic flavorants are being discovered and used. For example, vanilla used to be extracted from a particular **species** of tropical orchid and was therefore a rather expensive flavorant. However, a synthetic vanilla flavorant can now be manufactured from wood-pulp lignins, and this has made this pleasant flavor much more readily available than it used to be.

Nutrients

Many foods are fortified with minerals, vitamins, and other micronutrients. One such example is table salt, which has iodine added (as potassium iodide) to help prevent **goiter** in the general population. Goiter used to be relatively common but is now rare, in part because of the widespread use of iodized salt.

Other foods that are commonly fortified with minerals and vitamins include milk and margarine (with vitamins A and D), flour (with thiamine, riboflavin, niacin, iron), and some commercial breads and breakfast cereals (with various vitamins and minerals, particularly in some commercial cereal preparations). Micronutrient additives in these and other commercial foods are carefully formulated to help contribute to a balanced diet in their consumers. Nevertheless, some people believe that it is somehow un-natural and un-healthy to consume foods that have been adulterated in this manner, and they prefer to eat "natural" foods that do not have any vitamins or minerals added to them.

Preservatives

Preservatives are substances added to foods to prevent spoilage caused by bacteria, **fungi**, yeasts, insects, or other biological agents. Spoilage can lead to a decrease in the nutritional quality of foods, to the growth of food-poisoning **microorganisms** such as the botulism bacterium, or to the production of deadly chemicals, such as **aflatoxin**, that can be produced in stored grains and seeds (such as peanuts) by species of fungi.

Salt has long been used to preserve meat and fish, either added directly to the surface or by immersing the food in a briny solution. **Nitrates and nitrites** (such as sodium nitrate, or saltpetre) are also used to preserve meats, especially cured foods such as sausages, salamis, and hams. These chemicals are especially useful in inhibiting the growth of *Clostridium botulinum*, the bacterium that causes deadly botulism. Vinegar and wood **smoke** are used for similar purposes. **Sulfur dioxide**, sodium sulfite, and benzoic **acid** are often used as preservatives in fruit products, such beverages as wine and beer, and in ketchup, pickles, and spice preparations.

Anti-oxidants are chemicals added to certain foods to prevent a deterioration in their quality or flavor, occurring due to the exposure of fats and oils to atmospheric oxygen. Examples of commonly used antioxidants are ascorbic acid (or vitamin C), butylated hydroxyanisole (or BHA), butylated hydroxytoluene (or BHT), gallates, and ethoxyquin.

Stabilizers and emulsifiers

Stabilizers and emulsifiers are added to prepared foods to maintain suspensions of fats or oils in water matrices (or vice versa), or to prevent the caking of ingredients during storage or preparation. One example of an emulsifying additive is glyceryl monostearate, often added to stored starch

products to maintain their texture. Alginates are compounds added to commercial ice cream, salad dressing, and other foods to stabilize emulsions of oil- or fat-in-water during storage.

Colorants

Some prepared foods have colors added to "improve" their aesthetic qualities and thereby to make them more attractive to consumers. This practice is especially common in the preparation of confectionaries such as candies, chocolate bars, ice creams, and similar products, and in fancy cakes and pastries. Similarly, products such as ketchup and strawberry preserves have red dyes added to enhance their color, relishes and tinned peas have green colors added, and dark breads may contain brown colorants. Most margarines have yellow colors added, to make them appear more similar to butter. Artificial drinks and drink-mixes contain food colorants appropriate to their flavor--cherry and raspberry contain red dyes, and so forth.

Various chemicals are used as food colorants, some of them being extracted from plants (for example, yellow and orange carotenes), while many others are synthetic chemicals derived from **coal** tars and other organic substances. The acute toxicity (i.e., short-term **poisoning**) and chronic toxicity (i.e., longer-term damage associated with diseases, cancers, and developmental abnormalities) of these colorants are stringently tested on animals in the laboratory, and the substances must be demonstrated to be safe before they are allowed to be used as food additives. Still, some people object to having these chemicals in their food, and choose to consume products that are not adulterated with colorants.

Residues of pesticides, antibiotics, and growth hormones

Insecticides, fungicides, herbicides, and other pesticides are routinely used in modern, industrial agriculture. Some of these chemicals are persistent, because they do not quickly break down in the **environment** to simpler substances, and/or they do not readily wash off produce. The chemicals in such cases are called residues, and it is not unusual for them to be present on or in foodstuffs in low concentrations. The permissible residue levels allowed in foodstuffs intended for human consumption are closely regulated by government. However, not all foods can be properly inspected, so it is common for people to be routinely exposed to small concentrations of these chemicals in their diet.

In addition, most animals cultivated in intensive agricultural systems, such as **feedlots** and factory farms, are routinely treated with antibiotics in their feed. This is done to prevent outbreaks of **communicable diseases** under densely crowded conditions. Antibiotic use is especially common during the raising of chickens, turkeys, pigs, and cows. Small residues of these chemicals remain in the meat, eggs, milk, or other products of these animals, and are ingested by human consumers. Also, growth hormones are given to beef and dairy cows to increase their productivity. Small residues of these chemicals also occur in products eaten by consumers.

Strictly speaking, residues of pesticides, antibiotics, and growth hormones are not additives because they are not added directly to foodstuffs. Nevertheless, these chemicals are present in foods eaten by people, and many consumers find this to be objectionable. So-called organic foods are cultivated without the use of synthetic pesticides, antibiotics, or growth hormones, and many people prefer to eat these foods instead of the much more abundantly available foodstuffs that are typically sold in commercial outlets. (Note that the term "organic foods" is somewhat of a misnomer, because all foods are organic in nature. The phrase "organic" in this sense is used to refer to foods containing additives and/or residues, etc.)

Irradiation of food

Irradiation is a new technology that can be used to prevent spoilage of foods by sterilizing most or all of the microorganisms and insects that they may contain. This process utilizes gamma radiation, and it is not known to cause any chemical or physical changes in foodstuffs, other than the intended benefit of killing organisms that can cause spoilage. Although this process displaces some of the uses of preservative chemicals as food additives, irradiation itself is somewhat controversial. Even though there is no scientific evidence that **food irradiation** poses tangible risks to consumers, some people object to the use of this technology and prefer not to consume foodstuffs processed in this manner.

Food and Drug Administration

Founded in 1927, the Food and Drug Administration (FDA) is an agency of the Untied States **Public Health**

Service. One of the nation's oldest consumer protection agencies, the FDA is charged with enforcing the Federal Food, Drug, and Cosmetics Act, and other related public health laws. The agency assesses risks to the public posed by foods, drugs, and cosmetics, as well as medical devices, blood, and medications such as insulin which are made from living organisms. It also tests food samples for contaminants, sets labeling standards, and monitors the public health effects of drugs given to animals raised for food.

To carry out its mandate of consumer protection, the FDA employs over 9,000 investigators, inspectors, and scientists who collect domestic and imported product samples for examination by FDA scientists. The FDA has the power to remove from the market those foods, drugs, **chemicals**, or medical devices it finds unsafe. The FDA often seeks voluntary recall of the product by manufacturers, but the agency can also stop sales and destroy products through court action. About 3,000 products a year are found to be unfit for consumers and are withdrawn from the marketplace based on FDA action. Also, about 30,000 import shipments each year are detained at the port of entry on FDA orders.

FDA scientists analyze samples of products to detect contamination, or review test results submitted by companies seeking agency approval for drugs, vaccines, **food additives**, dyes, and medical devices. The FDA also operates the National Center for Toxicological Research at Jefferson, Arkansas, which conducts research to investigate the biological effects of widely used chemicals. The Agency's Engineering and Analytical Center at Winchester, Massachusetts, tests medical devices, radiation-emitting products, and radioactive drugs. The Bureau of Radiological Health was formed in 1971 to protect against unnecessary human exposure to radiation from electronic products such as microwave ovens.

The FDA is one of several federal organizations that oversees the safety of **biotechnology**, such as the industrial use of **microorganisms** to processes waste and water products.

In 1996, when the FDA declared that cigarettes and smokeless **tobacco** are nicotine-delivery devices, it took responsibility for regulating those products under the authority of the Federal Food, Drug, and Cosmetics Act. With regard to these products, the FDA has issued federal mandates concerning sales to minors, sales from vending machines, and advertising campaigns.

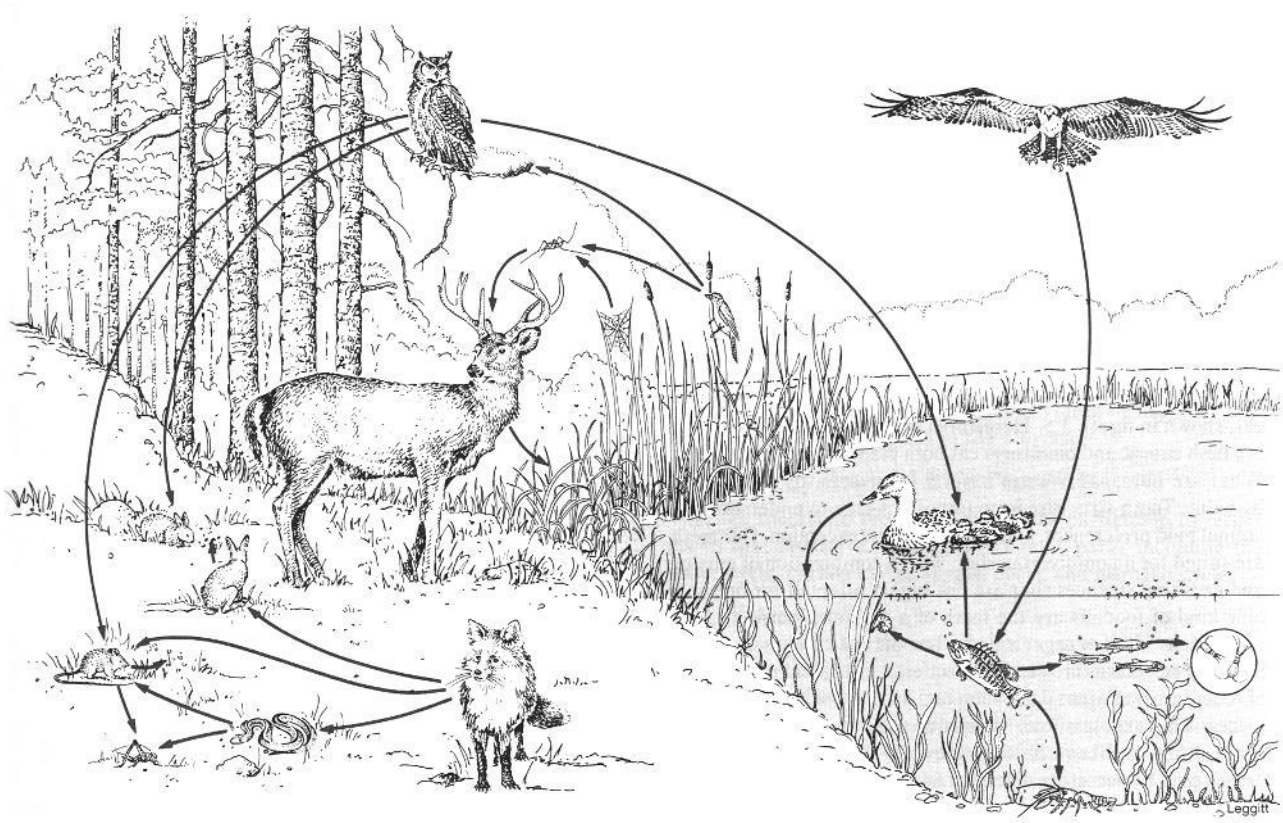
Food chain/web



Food chains and food webs are methods of describing an **ecosystem** by describing how energy flows from one **species** to another.

First proposed by the English zoologist Charles Elton in 1927, food chains and food webs describe the successive transfer of energy from plants to the animals that eat them, and to the animals that eat those animals, and so on. A food chain is a model for this process which assumes that the transfer of energy within the community is relatively simple. A food chain in a grassland ecosystem, for example, might be: Insects eat grass, and mice eat insects, and fox eat mice. But such an outline is not exactly accurate, and many more species of plants and animals are actually involved in the transfer of energy. Rodents often feed on both plants and insects, and some animals, such as predatory birds, feed on several kinds of rodents. This more complex description of the way energy flows through an ecosystem is called a food web. Food webs can be thought of as interconnected or intersecting food chains.

The components of food chains and food webs are producers, consumers, and **decomposers**. Plants and chemosynthetic bacteria are producers. They are also called primary producers or autotrophs ("self-nourishing") because they produce organic compounds from inorganic **chemicals** and outside sources of energy. The groups that eat these plants are called primary consumers or herbivores. They have adaptations that allow them to live on a purely vegetative diet which is high in cellulose. They usually have teeth modified for chewing and grinding; ruminants such as deer and cattle have well-developed stomachs, and lagomorphs such as rabbits have caeca which aid their digestion. Animals that eat herbivores are called secondary consumers or primary carnivores, and predators that eat these animals are called tertiary consumers. Decomposers are the final link in the **energy flow**. They feed on dead organic matter, releasing nutrients back into the ecosystem. Animals that eat dead plant and animal matter are called scavengers, and plants that do the same are known as saprophytes.

The components of food chains and food webs exist at different stages in the transfer of energy through an ecosystem. The position of every group of organisms obtaining their food in the same manner is known as a **trophic level**. The term comes from a Greek word meaning "nursing," and the implication is that each stage nourishes the next. The

In an ecosystem, food chains become interconnected to form food webs. (Illustration by Hans & Cassidy.)

first tropic level consists of autotrophs, the second herbivores, the third primary carnivores. At the final trophic level exists what is often called the "top predator." Organisms in the same trophic level are not necessarily connected taxonomically; they are connected ecologically, by the fact they obtain their energy in the same way. Their trophic level is determined by how many steps it is above the primary producer level. Most organisms occupy only one trophic level; however some may occupy two. Insectivorous plants like the venus flytrap are both primary producers and carnivores. Horseflies are another example: the females bite and draw blood, while the males are strictly herbivores.

In 1942, Raymond Lindeman published a paper entitled "The Tropic-Dynamic Aspect of Ecology." Although a young man and only recently graduated from Yale University, he revolutionized ecological thinking by describing ecosystems in the terminology of energy transformation. He used data from his studies of Cedar Bog Lake in Minnesota to construct the first energy budget for an entire ecosystem. He measured harvestable net production at three trophic levels, primary producer, herbivore, and carnivore. He did this by measuring gross production minus growth, reproduction, **respiration**, and excretion. He was able to calculate the assimilation efficiency at each tropic level, and the efficiency of energy transfers between each level. Lindeman's calculations are still widely regarded today, and his conclusions are usually generalized by saying that the ecological efficiency of energy transfers between trophic levels averages about 10%.

Lindeman's calculations and some basic laws about physics reveal important truths about food chains, food webs, and ecosystems in general. The First Law of Thermodynamics states that energy cannot be created or destroyed; energy input must equal energy output. The Second Law of Thermodynamics states that all physical processes proceed in such a way that the availability of the energy involved decreases. In other words, no transfer of energy is completely efficient. Using the generalized 10% figure from Lindeman's study, a hypothetical ecosystem with 1,000 kcal of energy available (net production) at the primary-producer level would mean that only 100 kcal would be available to the herbivores at the second trophic level, 10 kcal to the primary carnivores at the third level, and 1 kcal to the secondary carnivores at the fourth level. Thus, no matter how much energy is

assimilated by the autotrophs at the first level of an ecosystem, the eventual number of trophic levels is limited by the laws which govern the transfer of energy. The number of links in most natural food chains is four.

The relationships between trophic levels has sometimes been compared to a pyramid, with a broad base which narrows to an apex. Trophic levels represent successively narrowing sections of the pyramid. These pyramids can be described in terms of the number of organisms at each trophic level. This was first proposed by Charles Elton, who observed that the number of plants usually exceeded the number of herbivores, which in turn exceeded the number of primary carnivores, and so on. Pyramids of number can be inverted, particularly at the base; an example of this would be the thousands of insects which might feed on a single tree. The pyramid-like relationship between trophic levels can also be expressed in terms of the accumulated weight of all living matter, known as **biomass**. Although upper-level consumers tend to be large, the population of organisms at lower trophic levels are usually much higher, resulting in a larger combined biomass. Pyramids of biomass are not normally inverted, though they can be under certain conditions. In aquatic ecosystems, the biomass of the primary producers may be less than that of the primary consumers because of the rate at which they are being consumed; **phytoplankton** can be eaten so rapidly that the biomass of **zooplankton** and other herbivores are greater at any particular time. The relationship between trophic levels can also described in terms of energy, but pyramids of energy cannot be inverted. There will always be more energy at the bottom than there is at the top.

Humans are the top consumer in many ecosystems, and they exert strong and sometimes damaging pressures on food chains. For example, **overfishing** or **overhunting** can cause a large drop in the number of animals, resulting in changes in the food-web interrelationships. On the other hand, overprotection of some animals like deer or moose can be just as damaging. Another harmful influence is that of **biomagnification**. Toxic chemicals such as **mercury** and DDT released into the **environment** tend to become more concentrated as they travel up the food chain. Some ecologists have proposed that the **stability** of ecosystems is associated with the complexity of the internal structure of the food web and that ecosystems with a greater number of interconnections are more stable. Although more studies must be done to test this hypothesis, we do know that food chains in constant environments tend to have a greater number of species and more trophic links, whereas food chains in unstable environments have fewer species and trophic links.

Food irradiation

The treatment of food with **ionizing radiation** has been in practice for nearly a century since the first irradiation process patents were filed in 1905. Regular use of the technology in food processing started in 1963 when the U.S. **Food and Drug Administration** (FDA) approved the sale of irradiated wheat and wheat flour. Today irradiation treatment is used on a wide variety of food products and is regulated in the United States by the FDA under a Department of Health and Human Services regulation.

Irradiation of food has three main applications: extension of shelf life, elimination of insects, and the destruction of bacteria and other pathogens that cause foodborne illness. This final goal may have the most far-reaching implications for Americans; the U.S. Centers for Disease Control (CDC) estimate that 76 million Americans get sick, and 5,000 die each year from illnesses caused by foodborne **microorganisms**, such as *E. coli*, *Salmonella*, the botulism toxin, and other pathogens responsible for food **poisoning**.

Irradiation technology involves exposing food to ionizing radiation. The radiation is generated from gamma rays emitted by cobalt-60 or cesium-137, or from x rays or electron beams. The amount of radiation absorbed during irradiation processing is measured in units called RADs (radiant energy absorbed). One hundred RADs is equivalent to one Gray (Gy). Depending on the food product being irradiated, treatment can range from 0.05 to 30 kGy. A dosimeter, or film badge, verifies the kGy dose. The ionizing radiation displaces electrons in the food, which slows cell division and kills bacteria and pests.

The irradiation process itself is relatively simple. Food is packed in totes or containers, which are typically placed on a conveyer belt. Beef and other foods that require refrigeration are loaded into insulated containers prior to treatment. The belt transports the food bins through a lead-lined irradiation cell or chamber, where they are exposed to the ionizing radiation that kills the microorganisms. Several trips through the chamber may be required for full irradiation. The length of the treatment depends upon the food being processed

and the technology used, but each rotation takes only a few minutes.

The FDA has approved the use of irradiation for wheat and wheat powder, spices, **enzyme** preparations, vegetables, pork, fruits, poultry, beef, lamb, and goat meat. In 2000, the FDA also approved the use of irradiation to control salmonella in fresh eggs.

Labeling guidelines introduced by the Codex Alimentarius Commission, an international food standards organization sponsored jointly by the United Nations Food and Agricultural Organization (FAO) and the World Health Organization (WHO), requires that all irradiated food products and ingredients be clearly labeled as such for consumers. Codex also created the radura, a voluntary international symbol that represents irradiation. In the United States, the food irradiation process is regulated jointly by FDA and the **U.S. Department of Agriculture** (USDA). Facilities using radioactive sources such as cobalt-60 are also regulated by the **Nuclear Regulatory Commission** (NRC. The FDA regulates irradiation sources, levels, food types and packaging, as well as required recordkeeping and labeling. Records must be maintained and made available to FDA for one year beyond the shelf-life of the irradiated food to a maximum of three years. They must describe all aspects of the treatment and foods that have been irradiated must be denoted with the radura symbol and by the statement "Treated with radiation" or "Treated by irradiation". As of 2002, food irradiation is allowed in some 50 countries and is endorsed by the World Health Organization (WHO), and many other organizations.

New legislation entitled the "Farm Security and Rural Investment Act of 2002" (the Farm Bill) passed in May 2002 may soften the food irradiation standards. The Farm Bill calls for the Secretary of Health and Human Services and FDA to implement a new regulatory program for irradiated foods. The program will allow the food industry to instead label irradiated food as "pasteurized" as long as they meet appropriate food safety standards. As of the writing of this entry, these new guidelines had not been implemented.

Food that has been treated with ionizing energy typically looks and tastes the same as non-irradiated food. Just like a suitcase going through an airport x-ray machine, irradiated food does not come into direct contact with a radiation source and is not radioactive. However, depending on the strength and duration of the irradiation process, some slight changes in appearance and taste have been reported in some foods after treatment. Some of the flavor changes may be attributed to the generation of substances known as radiolytic products in irradiated foods.

When food products are irradiated the energy displaces electrons in the food and forms compounds called free radicals. The free radicals react with other molecules to form new stable compounds, termed radiolytic products. **Benzene**, formaldehyde, and **hydrogen** peroxide are just a few of the radiolytic products that may form during the irradiation process. These substances are only present in minute amounts, however, and the FDA reports that 90% of all radiolytic products from irradiation are also found naturally in food.

The chemical change that creates radiolytic products also occurs in other food processing methods, such as canning or cooking. However, about 10% of the radiolytic products found in irradiated food are unique to the irradiation process and little is known about the effects that they may have on human health. It should be noted, however, that the World Health Organization, the American Medical Association, the American Dietetic Association, and a host of other professional healthcare organizations endorse the use of irradiation as a food safety measure.

Treating fruit and vegetables with irradiation can also eliminate the need for chemical **fumigation** after harvesting. Produce shelf life is extended by the reduction and elimination of organisms that cause spoilage. It also slows cell division, thus delaying the ripening process, and in some types of produce irradiation extends the shelf life for up to a week. Advocates of irradiation claim that it is a safe alternative to the use of fumigants, several of which have been banned in the United States.

Nevertheless, irradiation removes some of the nutrients from foods, particularly vitamins A, C, E, and the B-Complex vitamins. Whether the extent of this **nutrient** loss is significant enough to be harmful is debatable. Advocates of irradiation say the loss is insignificant, and standard methods of cooking can destroy these same vitamins. However, research suggests that cooking an irradiated food may further increase the loss of nutrients.

Critics of irradiation also question the long-term safety of consumption of irradiated food and their associated radiolytic products. They charge that the technology does nothing to address the unsanitary food processing practices and inadequate inspection programs that breed foodborne pathogens.

Even if irradiation is 100% safe and beneficial there are numerous environmental concerns. Many opponents of irradiation cite the proliferation of radioactive material and the environmental hazards. The mining and on-site processing of radioactive materials are devastating to regional ecosystems. There are also safety hazards associated with the **transportation** of radioactive material, production of isotopes, and disposal.

Food policy

Through a variety of agricultural, economic, and regulatory programs which support or direct policies related to the production and distribution of food, the United States government has a large influence on how agriculture business is conducted. The government's major impact on agriculture is the setting of prices and mandates regarding how land can be used by farmers that participate in government programs. These policies can also have a large impact on the adoption or use of alternative practices and technologies that may be more efficient and sustainable in the world marketplace.

In the past, farm commodity programs have had a large influence in the past on the kinds and amounts of crops grown as well as on the choice of management practices used to grow them. Prices under government commodity programs have often been above world market prices which meant that many farmers felt compelled to preserve or build their farm commodity program base acres, since acreage determines program eligibility and future income. These programs strongly influenced land-use decisions on about two-thirds of the harvested cropland in the United States.

Price and income support programs for major commodities also influence growers not in the programs. For example, pork producers are not a part of a government program, and in the past they have paid higher feed prices because of high price supports on production of feed grains. At other times, particularly after the Food Security Act of 1985, they benefited from policies resulting in lower food costs. So as the government changes policy in one area, there can be widespread indirect impacts in other areas. For example, the federal dairy termination program, which ran from 1985–1987 was designed to reduce overproduction of milk. Those farmers who sold their milk cows and decided to produce hay for local cash markets caused a steep decline in the prices received by other established hay producers.

Federal policy evolved as a patchwork of individual programs, each created to address individual problems. There was not a coherent strategy to direct programs toward a common set of goals. Many programs such as **soil conservation** and export programs have had conflicting objectives, but attempts have now been made in the most current farm legislation to address some of these problems.

Government food policy has produced a wide variety of results. The policy has not only affected commodity prices and the level of output, but it has also shaped technological change, encouraged uneconomical capital investments in machinery and facilities, inflated the value of land, subsidized crop production practices that have led to resource degradation (such as **soil erosion** and surface and **groundwater pollution**), expanded the interstate highway system, financed **irrigation** projects, and promoted farm commodity exports. Together with other economic forces, government policy has had a far-reaching structural influence on agriculture, much of it unintended and unanticipated.

Federal commodity programs were put into place beginning in the 1930s, primarily with the Agriculture Adjustment Act of 1938. The purpose of these programs born out of the Depression was primarily to protect crop prices and farmer income which has been done by a number of programs over the years. A variety of methods have been used including setting prices, making direct payments to farmers, and subsidizing exports. However, by the mid-1980s and early 1990s, an increasing number of people felt that these programs impeded movement toward alternative types of agriculture, to the detriment of family farms and society in general.

Two components in particular were highlighted as being problems: base acre requirements and cross-compliance. All crop price and income support programs relied on the concept of an acreage base planted with a given commodity that would produce a predictable yield. Most of this acreage was planted to maximize benefits and was based on a five-year average. A farmer knew that if he/she reduced their acres for a given crop, they would not only lose the current year's benefits, but would also lose future benefits.

Cross-compliance was instituted in the Food Security Act of 1985. It was designed to control government payments and production by attaching financial penalties to the

expansion of program crop base acres. It served as an effective financial barrier to diversification of crops by stipulating that to receive any benefits from an established crop acreage base, the farmer must not exceed his or her acreage base for any other program crop. This had a profound impact on farmers and crop growers since about 70% of the United States' cropland acres were enrolled in the programs.

In addition to citing these problem areas, critics of food policy programs argued that many farmers faced economic penalties for adopting beneficial practices such as crop rotation or strip cropping, practices that in general reduce soil erosion and improve environmental quality. The economic incentives built into commodity programs, for example, encouraged heavier use of **fertilizer**, pesticides, and irrigation. These programs also encouraged surplus production, subsidized inefficient use of inputs, and they resulted in increased government expenditures. Critics argued that the rules associated with these programs discouraged farmers from pursuing alternative practices or crops, or technologies that might have proved more effective in the long term or that were more environmentally friendly.

Critics also contend that much of the research conducted over the past 40 years has responded to the needs of farmers operating under a set of economic and policy incentives that encouraged high yields without regard to the long-term environmental impacts. During the late 1980s and early 1990s, several **U.S. Department of Agriculture** research and education programs were instituted to determine whether current levels of production can be maintained with reduced levels of fertilizers and pesticides, to examine more intensive management practices, to increase understanding of biological principles, and to improve profitability per unit of production with less government support. As the impacts of the alternative production systems on the **environment** are evaluated, it will be important to have policies in place that will allow the farmer to easily adopt those practices that increase efficiency and reduce impacts. In a farm bill passed in 1996 there are provisions that change these commodity programs. Labeled the "right to farm provisions," these allow farmers to make decisions on what they grow and establish a phased seven-year reduction in price supports.

Food quality and safety are major concerns addressed as a part of federal policy. Programs addressing these concerns are primarily designed to prevent health risks and acute illnesses from chemical and microbial contaminants in food. Supporters say that this has provided the country with the safest food supply in the world. However, critics contend that a number of regulations do not enhance quality or safety and put farmers that use or would adopt alternative agricultural practices at a disadvantage. Several examples can be cited. Critics of government food policy point out that until recently, meat grading standards awarded producers of fatty beef which has been linked to the increased likelihood of heart disease.

The use of pesticides provides another example. The **Environmental Protection Agency** establishes **pesticide** residual tolerance levels in food which are monitored for compliance. For some types of risk, **cancer** in particular, there is a great deal of uncertainty, and critics point out which cosmetic standards that increase prices for fruits and vegetables may encourage higher risks of disease among consumers. Also, certain poultry slaughter practices can result in microbiological contamination. Of particular concern is salmonella food **poisoning** which has become widespread.

Government food policy heavily influences on-farm decision making. In some cases one part of the policy has negative or unintended consequences for another policy or segment of farmers. As we look to the future, the struggle will be to continue to provide a coherent, coordinated policy. The recent changes in policy will need to be evaluated from the standpoint of sustainability and environmental impacts.

Food waste

Waste food from residences, grocery stores, and food services accounts for nearly seven percent of the **municipal solid waste** stream. The per capita amount of food waste in municipal **solid waste** has been declining since 1960 due to increased use of **garbage** disposals and increased consumption of processed foods. Food waste ground in garbage disposals goes into sewer systems and thus ends up in **wastewater**. Waste generated by the food processing industry is considered to be industrial waste, and is not included in municipal solid waste estimates.

Waste from the food processing industry includes: vegetables and fruits unsuitable for canning or freezing; vegetable, fruit, and meat trimmings; and pomace from juice manufacturing. Vegetable and fruit processing waste is sometimes used as animal feed and waste from meat and seafood processing can be composted. Liquid waste from juice manufacturing can be applied to cropland as a **soil** amendment. Much of the waste generated by all types of food processing is wastewater due to such processes as washing, peeling, blanching, and cooling. Some food industries recycle

wastewaters back into their processes, but there is potential for more of this wastewater to be reused.

Grocery stores generate food waste in the form of lettuce trimmings, excess foliage, unmarketable produce, and meat trimmings. Waste from grocery stores located in rural areas is often used as hog or cattle feed, whereas grocery waste in urban areas is usually ground in garbage disposals. There is potential for more urban grocery store waste to be either used on farms or composted, but lack of storage space, odor, and **pest** problems prevent most of this waste from being recycled.

Restaurants and institutional cafeterias are the major sources of food service industry waste. In addition to food preparation wastes, they also generate large amounts of cooking oil and grease waste, post-consumer waste (uneaten food), and surplus waste. In some areas small amounts of surplus waste is utilized by feeding programs, but most waste generated by food services goes to landfills or into garbage disposals.

Most food waste is generated by sources other than households. However, a greater percentage of household food waste is disposed of because there is a higher rate of **recycling** of industrial and commercial food waste. Only a very small segment of households compost or otherwise recycle their food wastes.

Food-borne diseases

Food-borne diseases are illnesses caused when people consume contaminated food or beverages. Contamination is frequently caused by disease-causing **microbes** called pathogens. Other causes of food-borne diseases are poisonous **chemicals** or harmful substances in food and beverages. There are so many different pathogens that more than 250 food-borne illnesses have been described, according to the United States Centers for Disease Control and Prevention(CDC). CDC estimated that food-borne pathogens cause approximately 76 million illnesses, 5,000 deaths, 325,000 hospitalizations in the United States each year.

Most food-borne illnesses are infections caused by bacteria, viruses, and **parasites** such as ***Cryptosporidium***. Harmful toxins cause food poisonings. Since there are so many different types of food-borne illnesses, symptoms will vary. However, some early symptoms are similar because the microbe or toxin travels through the gastrointestinal tract. The initial symptoms of food-borne diseases are nausea, vomiting, abdominal cramps, and diarrhea.

According to CDC, the most common food-borne viruses are caused by three bacteria and a group of viruses. *Campylobacter* is a bacterium that lives in the intestines of healthy birds. It is also found in raw poultry meat. An infection is caused by eating undercooked chicken or food contaminated by juices from raw chicken. The bacterial **pathogen** causes fever, diarrhea, and abdominal cramps. *Campylobacter* is the primary cause of bacteria-related diarrhea illness throughout the world.

Salmonella is a bacterium that is prevalent in the intestines of birds, mammals, and reptiles. The bacterium spreads to humans through various foods. *Salmonella* causes the illness *salmonellosis*. Symptoms include fever, diarrhea, and abdominal cramps. This illness can result in a life-threatening infection for a person who is in poor health or has a weakened immune system.

E. coli O157:H7 is a bacterial pathogen that has a **reservoir** in cattle and similar animals. *E. coli* causes a serious illness. People become ill after eating food or drinking water that was contaminated with microscopic amounts of cow feces, according to CDC. A person often experiences severe and bloody diarrhea and painful abdominal cramps. Hemolytic urine syndrome (HUS) occurs in 3–5% of *E. coli* cases. This complication may occur several weeks after the first symptoms. HUS symptoms include temporary **anemia**, profuse bleeding, and kidney failure.

Food-borne illnesses are also caused by *Calicivirus*, which is also known as the Norwalk-like **virus**. This group of viruses is believed to spread from one person to another. An infected health service worker preparing a salad or sandwich could contaminate the food. According to CDC, infected fishermen contaminated oysters that they handled. These viruses are characterized by severe gastrointestinal illness. There is more vomiting than diarrhea, and the person usually recovers in two days.

The types and causes of food-borne illnesses have changed through the years. The pasteurization of milk, improved **water quality**, and safer canning techniques led to a reduction in the number of cases of common food-borne illness like typhoid fever, tuberculosis, and **cholera**. Cause of contemporary food-borne illnesses range from parasites living in imported food to food-processing techniques. An

outbreak of a diarrheal illness in 1996 and 1997 was attributed to *Cyclsopora*, a parasite that contaminated raspberries grown in Guatemala. That led to 2,500 confirmed infection cases in 21 states.

Food may be contaminated during processing. For example, the meat contained in one hamburger may come from hundreds of animals, according to CDC. An *E. coli* outbreaks during the 1990s were linked to hamburgers purchased at fast food restaurants.

Technology in the form of **food irradiation** may eliminate the pathogens that cause food-borne disease. Advocates say that radiating food with gamma rays is effective and can be done when the food is packaged. Opponents say the process is dangerous and could produce the free radicals that cause **cancer**.

CDC ranks "raw foods of animal origin" as the foods most likely to be contaminated. This category includes meat, poultry, raw eggs, raw shellfish, and unpasteurized milk. Furthermore, raw fruit and vegetables could also pose a health risk. Vegetables fertilized by manure can also be contaminated by the **fertilizer**. CDC said that some outbreaks of food-borne illness were traced to unsanitary processing procedure. Water quality was crucial when washing vegetables, as was chilling the produce after it was harvested.

Of particular concern are alfalfa sprouts and other raw sprouts. These vegetables sprout in conditions that are favorable to microbes. Sprouts are eaten raw, and the microbes can grow into a large number of pathogens.

CDC advises consumers to thoroughly cook meat, poultry, and eggs. Produce should be washed. Leftovers should be chilled promptly. CDC is part of the United States **Public Health Service**. It researches and monitors health issues. Federal regulation of food safety is the responsibility of agencies such as the **Food and Drug Administration**, the United States Department of Agriculture, and the National Marine Fisheries Service.

Foot and mouth disease

Foot-and-mouth disease (FMD), also called hoof-and-mouth disease, is a highly contagious and economically devastating viral disease of cattle, swine, and other cloven-hoofed (split-toed) ruminants, including sheep, goats, and deer. The disease is highly contagious, for nearly 100% of exposed animals become infected, and it spreads rapidly through susceptible populations. Although there is no cure for FMD, it is seldom fatal, but it can kill very young animals.

The initial symptoms of the disease include fever and blister-like lesions (vesicles). The vesicles rupture into erosions on the tongue, in the mouth, on the teats, and between the hooves. Vesicles that rupture **discharge** clear or cloudy fluid and leave raw, eroded areas with ragged fragments of loose tissue. Erosions in the mouth result in excessive production of sticky, foamy, stringy saliva, which is a characteristic of FMD. Another characteristic symptom is lameness with reluctance to move. Other possible symptoms and effects of FMD include elevated temperatures in the early stages of the disease for two to three days, abortion, low conception rates, rapid weight loss, and drop in milk production. FMD lasts for two to three weeks, with most animals recovering within six months. However, it can leave some animals debilitated, thus causing severe losses in the production of meat and milk. Even cows that have recovered seldom produce milk at their original rates. Animals grown for meat do not usually regain lost weight for many months. FMD can also lead to myocarditis, which is an inflammation of the muscular walls of the heart, and death, especially in newborn animals. Infected animals can spread the disease throughout their lives so the only way to stop an outbreak is to destroy the animals.

The **virus** that causes the disease survives in lymph nodes and bone marrow at neutral **pH**. There are at least seven types and many subtypes of the FMD virus. The virus persists in contaminated fodder and in the **environment** for up to one month, depending on the temperature and pH. FMD thrives in dark, damp places, like barns, and can be destroyed with heat, sunlight, and disinfectants.

The disease is not likely to affect humans, either directly or indirectly through eating meat from an infected animal, but humans can spread the virus to animals. FMD can remain in human nasal passages for at up to 28 hours. FMD viruses can be spread by other animals and materials to susceptible animals. The viruses can also be carried for several miles on the wind if environmental conditions are appropriate for virus survival. Specifically, an outbreak can occur when:

- people wearing contaminated clothes or footwear or using contaminated equipment pass the virus to susceptible animals

- animals carrying the virus are introduced into susceptible herds
- contaminated facilities are used to hold susceptible animals
- contaminated vehicles are used to move susceptible animals
- raw or improperly cooked **garbage** containing infected meat or animal products is fed to susceptible animals
- susceptible animals are exposed to contaminated hay, feedstuffs, or hides
- susceptible animals drink contaminated water
- a susceptible cow is inseminated by semen from an infected bull

Widespread throughout the world, FMD has been identified in Africa, South America, Middle East, Asia, and parts of Europe. North America, Central America, **Australia**, New Zealand, Chile, and some European countries are considered to be free of FMD. The United States has been free of FMD since 1929, when the last of nine outbreaks that occurred during the nineteenth and early twentieth centuries was eradicated.

In 2001, an FMD outbreak was confirmed in the United Kingdom, France, the Netherlands, the Republic of Ireland, Argentina, and Uruguay. Officials in the United Kingdom detected 2,030 cases of FMD, slaughtered almost four million animals, and took seven months to control the outbreak. The economic losses were estimated to be in the billions of pounds, and tourism in the affected countries was adversely affected. The outbreak was detected on February 20, 2001; no new cases were reported after September 30, 2001; on January 15, 2002, the British government declared the FMD outbreak to be over. The outbreak appeared to have started in a pig finishing unit in Northumberland, which was licensed to feed processed waste food. The disease appeared to have spread through two routes: through infected pigs who were sent to a slaughterhouse and through windborne spread to sheep on a nearby farm. These sheep entered the marketing chain and were sold in markets and through dealers, where they infected other sheep, people, and vehicles, spreading the FMD virus throughout England, Wales, southern Scotland. As the outbreak continued, cases were detected in other European countries.

The Animal and Plant Health Inspection Service (APHIS) of the United States Department of Agriculture (USDA) has developed a on-going comprehensive prevention program to protect American agriculture from FMD. APHIS continuously monitors for FMD cases worldwide. When FMD outbreaks are identified, APHIS initiates regulations that prohibit importation of live ruminants and swine and many animal products from the affected countries. In the 2001 outbreak in some **European Union** member countries, APHIS temporarily restricted importation of live ruminants and swine and their products from all European Union member states. APHIS officials are on duty at all United States land and maritime ports-of-entry to ensure that passengers, luggage, cargo, and mail are checked for prohibited agricultural products or other materials that could carry FMD. The USDA Beagle Brigade, dogs trained to sniff out prohibited meat products and other contraband items, are also on duty at airports to check incoming flights and passengers.

The cooperation of private citizens is a crucial component of the protection program. APHIS prevents travelers entering the United States from bringing any agricultural products that could spread FMD and other harmful agricultural pests and diseases. Therefore passengers must declare all food items and other materials of plant or animal origin that they are carrying. Prohibited agricultural products that are found are confiscated and destroyed. Passengers must also report any visits to farms or livestock facilities. Failure to declare any items may result in delays and fines up to $1,000. Individuals traveling from countries that have been designated as FMD-affected must have shoes disinfected if they have visited farms, ranches, or other high risk areas, such as zoos, circuses, fairs, and other facilities and events where livestock and animals are exhibited.

APHIS recommends that travelers should shower and shampoo prior to and again after returning to the United States from an FMD-affected country. They should also launder or dry clean clothes before returning to the United States. Full-strength vinegar can be used by passengers to disinfect glasses, jewelry, watches, belts, hats, cell phones, hearing aids, camera bags, backpacks, and purses. If travelers had visited a farm or had any contact with livestock on their trip, they should avoid contact with livestock, **zoo** animals, or **wildlife** for five days after their return. Although dogs and cats cannot become infected with FMD, their feet, fur, and bedding should be cleaned of excessive dirt or mud. Pet bedding should not contain straw, hay, or other plant materials. The pet should be bathed as soon as it reaches its final destination and be kept away from all livestock for at least five days after entering the United States.

In the United States, animal producers and private veterinarians also monitor domestic livestock for symptoms of FMD. Their surveillance activities are supplemented with the work of 450 specially trained animal disease diagnosticians from federal, state, and military agencies. These diagnosticians are responsible for collecting and analyzing samples from animals suspected of FMD infection. If an outbreak were confirmed, APHIS would quickly try to identify infected and exposed animals, establish and maintain quarantines, destroy all infected and exposed animals using humane euthanization procedures as quickly as possible, and dispose of the carcasses by an approved method such as **incineration** or burial. After cleaning and disaffection of facilities where the infected animals were housed, the facility

would be left vacant for several weeks. After this period, a few susceptible animals would be placed in the facility and observed for signs of FMD. A large area around the facility would be quarantined, where animal and human movement would be restricted or prohibited. In some cases, all susceptible animals within a two-mile radius would be also euthanized and disposed of properly by incineration or burial. In addition, APHIS has developed plans to pay affected producers the fair market value of their animals.

APHIS would consider vaccinating animals against FMD to enhance other eradication activities as well as to prevent spread to disease-free areas. However, vaccinated animals may still become infected and serve as a **reservoir** for the disease, even though they do not develop the disease symptoms themselves. Also for continued protective immunity, the vaccines must be given every few months.

APHIS is working with the U.S. Armed Forces to ensure that military vehicles and equipment are cleaned and disinfected before returning to the United States.

Preventing FMD from infecting and becoming established in an FMD-free area requires constant vigilance and a well-developed, thorough plan to control and eradicate any cases that might occur.

Stephen Alfred Forbes (1844 – 1930)

American entomologist and naturalist

Stephen Alfred Forbes, an entomologist and naturalist, was the son of Isaac Sawyer and Agnes (Van Hoesen) Forbes. Forbes was born at Silver Creek, Ill. His father was a farmer, and died when Stephen was 10 years old. An older brother, Henry, then 21 years old, had been independent since he was 14, working his way toward a college education, but on his father's death he abandoned his career, took the burden of his father's family on his shoulders, and supported and educated the children. He taught Stephen to read French, sent him to Beloit to prepare for college; and when the Civil War came he sold the farm and gave the proceeds (after the mortgage was paid) to his mother and sister for their support. Both brothers then joined the 7th Illinois Cavalry, Henry having retained enough money to buy horses for both. Stephen, enlisting at 17, was rapidly promoted, and at 20 became a captain in the regiment of which his brother ultimately became colonel. In 1862, while carrying dispatches, he was captured and held in a Confederate prison for four months. After liberation and three months in the hospital recuperating, he rejoined his regiment and served until the end of the war. He had learned to read Italian and Spanish in addition to French, before the war, and studied Greek while in prison.

He was a born naturalist. His farm life as a boy and his open-air life in the army intensified his interest in **nature**. After the close of the war, he began at once the study of medicine, entering the Rush Medical College where he nearly completed the course. His biographers have not as yet given the reason for the radical change in his plans which caused him to abandon medicine at this late stage in his education; but the writer has been told by his son, that it was "because of a series of incidents having to do mainly with operations without the use of anesthetics which convinced him that he was not temperamentally adapted to medical practice." His scientific interests, however, had been thoroughly aroused, and for several years while he taught school in southern Illinois, he carried on studies in natural history. In 1872 through the interest and influence of Dr. George Vasey, the well-known botanist, he was made curator of the Museum of State Natural History at Normal, Ill., and three years later was made instructor in zoology at the normal school. In 1877 the Illinois State Museum was established at Springfield; and the museum at Normal, becoming the property of the state, was made the Illinois State Laboratory of Natural History. Forbes was made its director. During these years he had been publishing the results of his researches rather extensively, and had gone into a most interesting and important line of investigation, namely the food of birds and fishes. He studied intensively the food of the different **species** of fish inhabiting Illinois waters and the food of the different birds. This study, of course, kept him close to entomology, and in 1884 he was appointed professor of zoology and entomology in the University of Illinois. The State Laboratory of Natural History was transferred to the university and in 1917 was renamed the Illinois Natural History Survey. He retained his position as chief, and held it up to the time of his death. He was appointed state entomologist in 1882 and served until 1917, when the position was merged in the survey. He retired from his teaching

position as an emeritus professor in 1921. He served as dean of the College of Science of the university from 1888 to 1905.

All through his career Forbes had been publishing his writings actively. As early as 1895, Samuel Henshaw, in his *Bibliography of the more Important Contributions to American Economic Entomology*, listed 101 titles. It is said that his bibliography runs to more than 500 titles. And the range of these titles is extraordinary; they include papers on entomology, ornithology, **limnology**, ichthyology, **ecology**, and other phases of biology. All of his work was characterized by remarkable originality and depth of thought. Forbes was the first writer and teacher in America to stress the study of ecology, and thus began a movement which has gained great headway. He published 18 annual entomological reports, all of which have been models. He was the first and leading worker in America on hydrobiology. He studied the fresh-water organisms of the inland waters and was the first scientist to write on the **fauna** of the **Great Lakes**. His work on the food of fishes was pioneer work and has been of very great practical value. Forbes was a charter member of the American Association of Economic Entomologists and served twice as its president. He was also a charter member of the Illinois Academy of Science; a member of the **National Academy of Sciences** and of the American Philosophical Society; and in 1928 was made an honorary member of the Fourth International Congress of Entomology. Indiana University gave him the degree of Ph.D., in 1884, on examination and presentation of a thesis. He married, on December 25, 1873, Clara Shaw Gaston, whose death preceded his by only six months. A son, Dr. Ernest B. Forbes of State College, Pa., and three daughters survived him.

Francois-Alphonse Forel (1841 – 1912)

Swiss professor of medicine

Francois-Alphonse Forel created a legacy by spending a lifetime studying a lake near which he lived. As the recognized founder of the science of the study of lakes, **limnology** Forel meticulously observed Lake Geneva. His observations not only contributed directly to the modern-day ecological and environmental direction. He helped to uncover the mysteries of the *seiche*—movements caused by wind or air pressure and that occur in lakes.

Forel was born in Morges, Switzerland on February 2, 1841. As a professor of anatomy and physiology at the University of Geneva, (also known as Lake Le man) he spent most of his time investigating the life and movement of the lake near his home, world-famous Lake Geneva. To that purpose he created the word "limnology" referring to the study of lakes. On April 2, 1869, he found a nematode worm 40 meters down in the lake. That discovery was the beginning of his lifelong work. Before publishing his first major work, Forel recruited help in describing the types of algae and invertebrate animals he had found. A preliminary study he published in 1874, *La Faune Profonde des Lacs Suisses,* (The Bottom Fauna of Swiss Lakes), provided the basis for his later work.

When his book on the lake, *Le Le man,* was published Forel himself noted there that, "This book is called *Limnological Monography.* I have to explain this new word and apologize, if it would be necessary. The aim of my description is a part of the Earth, that's geography. But the geography of the ocean is called oceanography. But a lake, as big it is, is by not means an ocean; its limited area give it a special characteristic, which is very different of the one of the endless ocean. I had to find a more modest word to describe my work, like the word *limnography.* But, because a limnograph is a tool to measure the water level of lakes, I had to fabricate the new word **limnology**. The limnology is in fact the *oceanography of the lakes.*" A second book, *Handbuch der Seenkunde* (Handbook of Lake Studies) also became a standard work in the study of lakes. According to Ayer Company Publishers—the publisher that reprinted the work in 1978—Forel realized that his original work was an encyclopedia which might not hold the interest of students. He published his handbook to be used as the first textbook for the study of limnology.

Forel died on August 7, 1912. In 1970 his work was honored when the F.-A. Forel Institute was founded in his honor by Professor Jean-Pierr Vernet who directed the laboratory until 1995. The institute became a part of the Earth Sciences department of the University of Geneva in 1980, and plays a vital role in the International Commission for the Protection of Lake Geneva's water (CIPEL). The active research that occurs through the institute includes limnology, environmental geochemistry, **ecotoxicology**, and quaternary geology. It is also the home of the secretariat of the Center of Earth and Environmental Sciences Studies

(CESNE) and the Diplome d'etudes en sciences naturelles de l'environment (DESNE).

One of the other ways in which Forel has been honored is the use of his name added to a device known as the **Forel-Ule Color Scale.** According to the Marine Educatin and Research Program at Occidental College, the scale is ued in marine studies, and consists of a series of numbered tubes (from 1 to 22) that contain various shades of colored fluids that range from blue (lowest numbers) through green, yellow, brown, and red (highest numbers).

Dave Foreman (1946 –)

American radical environmental activist

Dave Foreman is a self-described radical environmentalist, Co-founder of **Earth First!**, and a leading defender of "monkey-wrenching" as a direct-action tactic to slow or stop **strip mining**, clear-cut **logging** of old-growth forests, the damming of wild rivers, and other environmentally destructive practices.

The son of a United States Air Force employee, Foreman traveled widely while growing up. In college he chaired the conservative Young Americans for Freedom and worked in the 1964 presidential election campaign of Senator Barry Goldwater. In the 1970s Foreman was a conservative Republican and moderate environmentalist who worked for the **Wilderness Society** in Washington, D.C. He came to believe that the **petrochemical**, logging, and mining interests were "extremists" in their pursuit of profit, and that government agencies—the **Forest Service**, the **Bureau of Land Management**, the **U.S. Department of Agriculture**, and others—were "gutless" and unwilling or unable to stand up to wealthy and powerful interests intent upon profiting from the destruction of American **wilderness**. Well-meaning moderate organizations like the **Sierra Club**, **Friends of the Earth**, and the Wilderness Society were, with few exceptions, powerless to prevent the continuing destruction. What was needed, Foreman reasoned, was an immoderate and unrespectable band of radical environmentalists like those depicted in Edward Abbey's novel *The Monkey Wrench Gang* (1975) to take direct action against anyone who would destroy the wilderness in the name of "development." With several like-minded friends, Foreman founded Earth First!, whose motto is "No compromise in defense of Mother Earth."

From the beginning, Earth First! was unlike any other radical group. It did not issue manifestoes or publish position papers; it had "no officers, no bylaws or constitution, no incorporation, no tax status; just a collection of women and men committed to the Earth." Earth First!, Foreman wrote, "would be big enough to contain street poets and cowboy bar bouncers, agnostics and pagans, vegetarians and raw steak eaters, pacifists and those who think that turning the other cheek is a good way to get a sore face." Its weapons would include "monkey-wrenching," civil disobedience, music, "media stunts [to hold] the villains up to ridicule," and self-deprecating humor: "Radicals frequently verge toward a righteous seriousness. But we felt that if we couldn't laugh at ourselves we would be merely another bunch of dangerous fanatics who should be locked up (like the oil companies). Not only does humor preserve individual and group sanity, it retards hubris, a major cause of environmental rape, and it is also an effective weapon." But besides humor, Foreman called for "fire, passion, courage, and emotionalism...We [environmentalists] have been too reasonable, too calm, too understanding. It's time to get angry, to cry, to let rage flow at what the human **cancer** is doing to Mother Earth."

In 1987 Foreman published *Ecodefense: A Field Guide to Monkeywrenching*, in which he described in detail the tools and techniques of environmental sabotage or **monkey-wrenching**. These techniques included "spiking" old-growth **redwoods** and Douglas firs to prevent loggers from felling them; "munching" logging roads with nails; sabotaging bulldozers and other earth-moving equipment; pulling up surveyors' stakes; and toppling high-voltage power lines. These tactics, Foreman said, were aimed at property, not at people. But critics quickly charged that loggers' lives and jobs were endangered by tree-spiking and other techniques

that could turn deadly. Moderate or mainstream environmental organizations joined in condemning the confrontational tactics favored by Foreman and Earth First!

In his autobiography *Confessions of an Eco-Warrior* (1991) Foreman defends monkey-wrenching as an unfortunate tactical necessity that has achieved its primary purpose of attracting the attention of the American people and the media to the destruction of the nation's remaining wilderness. It also attracted the attention of the FBI, whose agents arrested Foreman at his home in 1989 for allegedly financing and encouraging *ecoteurs* (ecological saboteurs) to topple high-voltage power poles. Foreman was put on trial to face felony charges, which he denied. The charges were questioned when it was disclosed that an FBI informant had infiltrated Earth First! with the intention of framing Foreman and discrediting the organization. In a plea bargain, Foreman pleaded guilty to a lesser charge and received a suspended sentence.

Foreman left Earth First! to found and direct The Wildlands Project in Tucson, Arizona. He continues to lecture and write about the protection of the wilderness.

Forest and Rangeland Renewable Resources Planning Act (1974)

The Forest and Rangeland Renewable Resources Planning Act (RPA) was passed in response to the growing tension between the timber industry and environmentalists in the late 1960s and the early 1970s. These tensions can be traced to increased controversy over and restrictions on timber harvesting on the national forests, due especially to **wilderness** designations and study areas and **clear-cutting**. These environmental restrictions, coupled with a dramatic increase in the price of timber in 1969, made Congress receptive to timber industry demands for a steadier supply of timber. Numerous bills addressing timber supply were introduced and debated in Congress, but none passed due to strong environmental pressure. A task force appointed by President Richard Nixon, the President's Panel on Timber and the Environment, delivered its recommendations in 1973, but these were geared toward dramatically increased harvests from the national forests, and hence were also unacceptable to environmentalists.

One aspect of the various proposals that proved to be acceptable to all interested parties—the timber industry, environmentalists, and the Forest Service—was increased long-range resource planning. Senator Hubert Humphrey of Minnesota drafted a bill creating such a program and helped guide it to passage in Congress. RPA planning is based on a two-stage process, with a document accompanying each stage. The first stage is called the *Assessment*, which is an inventory of the nation's forest and range resources (public and private). The second stage, which is based on the *Assessment*, is referred to as the *Program*. Based on the completed inventory, the **Forest Service** provides a plan for the use and development of the available resources. The *Assessment* is to be done every 10 years. A *Program* based on the *Assessment* will be completed every five years. This planning was to be done by interdisciplinary teams and to incorporate widespread public involvement.

The RPA was quite popular with the Forest Service since the plans generated through the process gave the agency a solid foundation to base its budget requests on, increasing the likelihood of increased funding. This has proved to be successful, as the Forest Service budget increased dramatically in 1977, and the agency fared much better than other resource agencies in the late twentieth century.

The RPA was amended by the **National Forest Management Act** of 1976. Based on this law, in addition to the broad national planning mandated in the 1974 law, an *Assessment* and *Program* was required for each unit of the **national forest** system. This has allowed the Forest Service to use the plans to help shield itself from criticism. Since these plans address all uses of the forests, and make budget recommendations for these uses, if Congress does not fund these recommendations, the Forest Service can point to Congress as the culprit. However, the plans have also been more visible targets for interest group criticism.

Overall, the RPA has met with mixed results. The Forest Service has received increased funds and the planning process has been expanded to each national forest unit, but planning at such a scale is a difficult task. The act has also led to increased controversy and to increased bureaucracy. Perhaps most importantly, planning cannot solve a problem based on conflicting values, commodity use versus forest preservation, which is at the heart of **forest management** policy. *See also* Old-growth forest

Forest decline

In recent decades there have been observations of widespread declines in vigor and **dieback** of mature forests in many parts of the world. In many cases, **pollution** may be a factor contributing to forest decline, for example in regions where **air quality** is poor because of acidic deposition or contamination with **ozone**, **sulfur dioxide**, **nitrogen** compounds, or metals. However, forest decline also occurs in some places where the air is not polluted, and in these cases it has been suggested that the phenomenon is natural.

Forest decline is characterized by a progressive, often rapid deterioration in the vigor of trees of one or several **species**, sometimes resulting in mass **mortality** (or dieback) within stands over a large area. Decline often selectively affects mature individuals, and is thought to be triggered by a particular stress or a combination of stressors, such as severe weather, **nutrient** deficiency, toxic substances in **soil**, and **air pollution**. According to this scenario, excessively stressed trees suffer a large decline in vigor. In this weakened condition, trees are relatively vulnerable to lethal attack by insects and **microbial pathogens**. Such secondary agents may not be so harmful to vigorous individuals, but they can cause the death of severely stressed trees.

The preceding is only a hypothetical etiology of forest dieback. It is important to realize that although the occurrence and characteristics of forest decline can be well documented, the primary environmental variable(s) that triggers the decline disease are not usually known. As a result, the etiology of the decline syndrome is often attributed to a vague but unsubstantiated combination of biotic and abiotic factors.

The symptoms of decline differ among tree species. Frequently observed effects include: (1) decreased productivity; (2) chlorosis, abnormal size or shape, and premature abscission of foliage; (3) a progressive death of branches that begins at the extremities and often causes a "stag-headed" appearance; (4) root dieback; (5) an increased frequency of secondary attack by fungal pathogens and defoliating or wood-boring insects; and (6) ultimately mortality, often as a stand-level dieback.

One of the best-known cases of an apparently natural forest decline, unrelated to human activities, is the widespread dieback of birches that occurred throughout the northeastern United States and eastern Canada from the 1930s to the 1950s. The most susceptible species were yellow (*Betula alleghaniensis*) and paper birch (*B. papyrifera*), which were affected over a vast area, often with extensive mortality. For example, in 1951 at the time of peak dieback in Maine, an estimated 67% of the birch trees had been killed. In spite of considerable research effort, a single primary cause has not been determined for birch dieback. It is known that a heavy mortality of fine roots usually preceded deterioration of the above-ground tree, but the environmental cause(s) of this effect are unknown, although deeply frozen soils caused by a sparse winter snow cover are suspected as being important. No biological agent was identified as a primary predisposing factor, although fungal pathogens and insects were observed to secondarily attack weakened trees and cause their death.

Another apparently natural forest decline is that of ohia (*Metrosideros polymorpha*), an **endemic species** of tree usually occurring in monospecific stands, that dominates the native forest of **Hawaiian Islands**. There are anecdotal accounts of events of widespread mortality of ohia extending back at least a century, but the phenomenon is probably more ancient than this. The most recent widespread decline began in the late 1960s and resulted in about 200 mi^2 (518 km^2) of forest with symptoms of ohia decline in a 1982 survey of 308 mi^2 (798 km^2). In most declining stands only the canopy individuals were affected. Understory saplings and seedlings were not in decline, and in fact were released from competitive stresses by dieback of the overstory.

An hypothesis to explain the cause of ohia decline has been advanced by D. Mueller-Dombois and co-workers, who believe that the stand-level dieback is caused by the phenomenon of "cohort senescence." This is a stage of the life history of ohia characterized by a simultaneously decreasing vigor in many individuals, occurring in old-growth stands. The development of senescence in individuals is governed by genetic factors, but the timing of its onset can be influenced by environmental stresses. The decline-susceptible, over mature, life history stage follows a more vigorous, younger, mature stage in an even-aged stand of individuals of the same generation (i.e., a cohort) that had initially established following a severe disturbance. In Hawaii, lava flows, events of deposition of volcanic ash, and hurricanes are natural disturbances that initiate **succession**. Sites disturbed in this way are colonized by a cohort of ohia individuals, which produce an even-aged stand. If there is no intervening catastrophic disturbance, the stand matures, then becomes senescent and enters a decline and dieback phase. The original stand is then replaced by another ohia forest

comprised of an advance regeneration of individuals released from the understory. Therefore, according to the cohort senescence theory, the ohia dieback should be considered to be a characteristic of the natural population dynamics of the species.

Other forest declines are occurring in areas where the air is contaminated by various potentially toxic **chemicals**, and these cases might be triggered by air pollution. In North America, prominent declines have occurred in ponderosa pine (*Pinus ponderosa*), red spruce (*Picea rubens*) and sugar maple (*Acer saccharum*). In western Europe, Norway spruce (*Picea abies*) and beech (*Fagus sylvatica*) have been severely affected.

The primary cause of the decline of ponderosa pine in stands along the western slopes of the mountains of southern California is believed to be the toxic effects of ozone. Ponderosa pine is susceptible to the effects of this gas at the concentrations that are commonly encountered in the declining stands, and the symptomalogy of damage is fairly clear.

In the other cases of decline noted above that are putatively related to air pollution, the evidence so far is less convincing. The recent forest damage in Europe has been described as a "new" decline syndrome that may in some way be triggered by stresses associated with air pollution. Although the symptoms appear to be similar, the "new" decline is believed to be different from diebacks that are known to have occurred historically and are believed to have been natural. The modern decline syndrome was first noted in fir (*Abies alba*) in Germany in the early 1970s. In the early 1980s a larger-scale decline was apparent in Norway spruce, the most commercially-important species of tree in the region, and in the mid 1980s decline became apparent in beech and oak (*Quercus* spp.).

Decline of this type has been observed in countries throughout Europe, extending at least to western Russia. The decline has been most intensively studied in Germany, which has many severely damaged stands, although a widespread dieback has not yet occurred. Decline symptoms are variable in the German stands, but in general: (1) mature stands older than about 60 years tend to be more severely affected; (2) dominant individuals are relatively vulnerable; and (3) individuals located at or near the edge of the stand are more-severely affected, suggesting that a shielding effect may protect trees in the interior. Interestingly, epiphytic **lichens** often flourish in badly damaged stands, probably because of a greater availability of light and other resources caused by the diminished cover of tree foliage. In some respects this is a paradoxical observation, since lichens are usually hypersensitive to air pollution, especially toxic gases.

From the information that is available, it appears that the "new" forest decline in Europe is triggered by a variable combination of environmental stresses. The weakened trees then decline rapidly, and may die as a result of attack by secondary agents such as fungal disease or insect attack. Suggestions of the primary inducing factor include gaseous air pollutants, **acidification**, toxic metals in soil, nutrient imbalance, and a natural climatic effect, in particular **drought**. However, there is not yet a consensus as to which of these interacting factors is the primary trigger that induces forest decline in Europe, and it is possible that no single stress will prove to be the primary cause. In fact, there may be several "different" declines occurring simultaneously in different areas.

The declines of red spruce and sugar maple in eastern North America involve species that are long-lived and shade-tolerant, but shallow-rooted and susceptible to drought. The modern epidemic of decline in sugar maple began in the late 1970s and early 1980s, and has been most prominent in Quebec, Ontario, New York, and parts of New England. During the late 1980s and early 1990s, the decline appeared to reverse, and most stands became more healthy. The symptoms are similar to those described for an earlier dieback, and include abnormal coloration, size, shape, and premature abscission of foliage, death of branches from the top of the tree downward, reduced productivity, and death of trees. There is a frequent association with the pathogenic fungus *Armillaria mellea*, but this is believed to be a secondary agent that only attacks weakened trees. Many declining stands had recently been severely defoliated by the forest tent caterpillar (*Malacosoma disstria*), and many stands were tapped each spring for sap to produce maple sugar. Because the declining maple stands are located in a region subject to a high rate of **atmospheric deposition** of acidifying substances, this has been suggested as a possible predisposing factor, along with soil acidification and mobilization of available **aluminum**. Natural causes associated with **climate**, especially drought, have also been suggested. However, little is known about the modern sugar maple decline, apart from the fact that it occurred extensively; no conclusive statements can yet be made about its causal factor(s).

The stand-level dieback of red spruce has been most frequent in high-elevation sites of the northeastern United States, especially in upstate New York, New England, and the mid- and southern-Appalachian states. These sites are variously subject to acidic precipitation (mean annual **pH** about 4.0–4.1), to very acidic fog water (pH as low as 3.2–3.5), to large depositions of sulfur and nitrogen from the **atmosphere**, and to stresses from metal toxicity in acidic soil.

Declines of red spruce are anecdotally known from the 1870s and 1880s in the same general area where the modern decline is occurring. Up to one-half of the mature red spruce in the Adirondacks of New York was lost during that early episode of dieback, and there was also extensive damage in New England. As with the European forest de-

cline, the "old" and "new" episodes appear to have similar symptoms, and it is possible that both occurrences are examples of the same kind of disease.

The hypotheses suggested to explain the initiation of the modern decline of red spruce are similar to those proposed for European forest decline. They include acidic deposition, soil acidification, aluminum toxicity, drought, winter injury exacerbated by insufficient hardiness due to nitrogen fertilization, **heavy metals** in soil, nutrient imbalance, and gaseous air pollution. Climate change, in particular a long term warming that has occurred subsequent to the end of the Little **Ice Age** in the early 1800s, may also be important.

At present, not enough is known about the etiology of the forest declines in Europe and eastern North America to allow an understanding of possible role(s) of air pollution and of natural environmental factors. This does not necessarily mean that air pollution is not involved. Rather, it suggests that more information is required before any conclusive statements can be made regarding the causes and effects of the phenomenon of forest decline. *See also* Forest management

Forest management

The question of how forest resources should be used goes beyond the science of growing and harvesting trees; forest management must solve the problems of balancing economic, aesthetic, and biological value to entire ecosystems. The earliest forest managers in North America were native peoples, who harvested trees for building and burned forests to make room for grazing animals. But many native populations were wiped out by European diseases soon after Europeans arrived. By the mid-nineteenth century, it became apparent to many Americans that overharvesting of timber along with wasteful practices, such as uncontrolled burning of **logging** waste, was denuding forests and threatening future ecological and economic **stability**. The **Forest Service** (established in 1905) began studying ways to preserve forest resources for their economic as well as aesthetic, recreational, and **wilderness** value.

From the 1600s to 1820s, 370 million acres (150 million ha) of forests—about 34% of the United States' total—were cleared, leaving about 730 million acres (296 million ha) today. Only 10–15% of the forests have never been cut. Many previously harvested areas, however, have been replanted and the annual growth now exceeds harvest overall. But the nature of the forests has been altered, many believe for the worse. If logging of old-growth forests were to continue at the rate maintained during the 1980s, all remaining unprotected stands would be gone by 2015. Some 33,000 timber-related jobs could also be lost during that time, not just from environmental protection but also from over-harvesting, increased mechanization, and increasing reliance on foreign processing of whole logs cut from private lands. Recent federal and court decisions, most notably to protect the **northern spotted owl** in the United States, have slowed the pace of old-growth harvesting and for now has put more old forests under protection. But the questions of how to use forest resources is still under fierce debate.

For decades, **clear-cutting** of tracts has been the standard forestry management practice. Favored by timber companies, clear-cutting takes virtually all material from a tract. But clear-cutting has come under increasing criticism from environmentalists, who point out that the practice replaces mixed-age, biologically diverse forests with single-age, single or few **species** plantings. Clear-cutting also relies heavily on roads to haul out timber, causing root damage, **topsoil erosion**, and **siltation** of streams. Industry standards such as "best management practices (BMPs)" prevent most erosion and siltation by keeping roads away from stream beds. But BMPs only address **water quality**. Clear-cutting also removes small trees, snags, boles, and woody debris that are important to invertebrates and **fungi**.

Rather than focusing on what is removed from a forest, sustainable forest management focuses on what is left behind. In **sustainable forestry**, tracts are never clear-cut: instead, individual trees are selected and removed to maintain diversity and health of the remaining **ecosystem**. Such methods avoid artificial replanting, herbicides, insecticides, and fertilizers. However, much debate remains on which trees and how many are chosen for harvesting under sustainable forestry.

In a new management style known most commonly as new forestry, 85–90% of trees on a site are harvested, and the land is left alone for decades to recover. Proponents say this method would cut down on erosion and increase diversity left behind on a tract, especially where one or two species dominate. The Forest Service and some Northwest states are studying new forestry, but environmentalists say too little is known about its effects on old-growth stands to use the

practice. Timber companies say more and larger tracts would have to be harvested under new forestry to meet demand.

Those who make their living from America's forests, and those who place value on the biological ecosystems they support, must resolve the debate on how to best preserve our forests. One-third of forest resources now come from Forest Service lands, and the debate is an increasingly public one, involving interests ranging from the **Sierra Club** and sporting clubs to the **Environmental Protection Agency** (EPA), the Agriculture Department (and its largest agency, the Forest Service), and timber companies and their employees. The future of our forests depends on balancing real short-term needs with the high price of long-term forest health.

Forest Service

The **national forest** system in the United States must be considered one of the great success stories of the **conservation** movement. This remains true despite the continual controversies that seem to accompany administration of national forest lands by the United States Forest Service.

The roots of the Forest Service began with the appointment in 1876 of Franklin B. Hough as a "forestry agent" in the **U.S. Department of Agriculture** to gather information about the nation's forests. Ten years later, Bernhard E. Fernow was appointed chief of a fledgling Division of Forestry. Part way through Fernow's tenure, Congress passed the Forest Reserve Act of 1891, which authorized the president to withdraw lands from the public domain to establish federal forest reserves. The public lands were to be administered, however, by the General Land Office in the **U.S. Department of the Interior**.

Gifford Pinchot succeeded Fernow in 1899 and was Chief Forester when President **Theodore Roosevelt** approved the transfer of 63 million acres (25 million ha) of forest reserves into the Department of Agriculture in 1905. That same year, the name of the Bureau of Forestry was changed to the United States Forest Service. Two years later, the reserves were redesignated national forests.

The Forest Service today is organized into four administrative levels: the office of the Chief Forester in Washington, D.C.; nine regional offices; 155 national forests; and 637 ranger districts. The Forest Service also administers twenty national **grasslands**. In addition, a research function is served by a forest products laboratory in Madison, Wisconsin, and eight other field research stations.

These lands are used for a wide variety of purposes and given official statutory status with the passage of the **Multiple Use-Sustained Yield Act** of 1960. That act officially listed five uses--timber, water, range, **wildlife**, and recreation--to be administered on national forest lands. **Wilderness** was later included. Forest Service now administers more than 34 million acres (14 million ha) in 387 units of the wilderness preservation system.

Despite a professionally trained staff and a sustained spirit of public service, Forest Service administration and management of national forest lands has been controversial from the beginning. The agency has experienced repeated attempts to transfer it to the Department of the Interior (or once to a new Department of Natural Resources); its authority to regulate grazing and timber use, including attempts to transfer national forest lands into private hands, has been frequently challenged and some of the Service's management policies have been the center of conflict. These policies have included **clear-cutting** and "subsidized" **logging**, various **recreation** uses, preservation of the **northern spotted owl**, and the cutting of old-growth forests in the Pacific Northwest.

Dr. Dian Fossey (1932 – 1985)

American naturalist and primatologist

Dian Fossey is remembered by her fellow scientists as the world's foremost authority on mountain gorillas. But to the millions of **wildlife** conservationists who came to know Fossey through her articles and book, she will always be remembered as a martyr. Throughout the nearly 20 years she spent studying mountain gorillas in central Africa, the American primatologist tenaciously fought the poachers and bounty hunters who threatened to wipe out the endangered primates. She was brutally murdered at her research center in 1985 by what many believe was a vengeful poacher.

Fossey's dream of living in the wilds of Africa dates back to her lonely childhood in San Francisco. She was born in 1932, the only child of George, an insurance agent, and Kitty, a fashion model, (Kidd) Fossey. The Fosseys divorced when Dian was six years old. A year later, Kitty married a wealthy building contractor named Richard Price. Price was a strict disciplinarian who showed little affection for his stepdaughter. Although Fossey loved animals, she was allowed to have only a goldfish. When it died, she cried for a week.

Fossey began her college education at the University of California at Davis in the preveterinary medicine program. She excelled in writing and botany, she failed chemistry and physics. After two years, she transferred to San Jose State University, where she earned a bachelor of arts degree in occupational therapy in 1954. While in college, Fossey became a prize-winning equestrian. Her love of horses in 1955 drew her from California to Kentucky, where she directed the occupational therapy department at the Kosair Crippled Children's Hospital in Louisville.

Fossey's interest in Africa's gorillas was aroused through primatologist George Schaller's 1963 book, *The Mountain Gorilla: Ecology and Behavior.* Through Schaller's book, Fossey became acquainted with the largest and rarest of three subspecies of gorillas, *Gorilla gorilla beringei.* She learned that these giant apes make their home in the mountainous forests of Rwanda, Zaire, and Uganda. Males grow up to 6 ft (1.8 m) tall and weigh 400 lb (182 kg) or more. Their arms span up to 8 ft (2.4 m). The smaller females weigh about 200 lb (91 kg).

Schaller's book inspired Fossey to travel to Africa to see the mountain gorillas in their homeland. Against her family's advice, she took out a three-year bank loan for $8,000 to finance the seven-week safari. While in Africa, Fossey met the celebrated paleoanthropologist Louis Leakey, who had encouraged **Jane Goodall** in her research of **chimpanzees** in Tanzania. Leakey was impressed by Fossey's plans to visit the mountain gorillas.

Those plans were nearly destroyed when she shattered her ankle on a fossil dig with Leakey. But just two weeks later, she hobbled on a walking stick up a mountain in the Congo (now Democratic Republic of the Congo) to her first encounter with the great apes. The sight of six gorillas set the course for her future. "I left Kabara (gorilla site) with reluctance but with never a doubt that I would, somehow, return to learn more about the gorillas of the misted mountains," Fossey wrote in her book, *Gorillas in the Mist.*

Her opportunity came three years later, when Leakey was visiting Louisville on a lecture tour. Fossey urged him to hire her to study the mountain gorillas. He agreed, if she would first undergo a preemptive appendectomy. Six weeks later, he told her the operation was unnecessary; he had only been testing her resolve. But it was too late. Fossey had already had her appendix removed.

The L.S.B. Leakey and the Wilkie Brothers foundations funded her research, along with the National Geographic Society. Fossey began her career in Africa with a brief visit to Jane Goodall in Tanzania to learn the best methods for studying primates and collecting data.

Fossey set up camp early in 1967 at the Kabara meadow in Zaire's Parc National des Virungas, where Schaller had conducted his pioneering research on mountain gorillas a few years earlier. The site was ideal for Fossey's research. Because Zaire's park system protected them against human intrusion, the gorillas showed little fear of Fossey's presence. Unfortunately, civil war in Zaire forced Fossey to abandon the site six months after she arrived.

She established her permanent research site September 24, 1967, on the slopes of the Virunga Mountains in the tiny country of Rwanda. She called it the Karisoke Research Centre, named after the neighboring Karisimbi and Visoke mountains in the Parc National des Volcans. Although Karisoke was just five miles from the first site, Fossey found a marked difference in Rwanda's gorillas. They had been harassed so often by poachers and cattle grazers that they initially rejected all her attempts to make contact.

Theoretically, the great apes were protected from such intrusion within the park. But the government of the impov-

Dian Fossey photographing mountain gorillas in Zaire. (AP/Wide World Photos. Reproduced by permission.)

erished, densely populated country failed to enforce the park rules. Native Batusi herdsmen used the park to trap antelope and buffalo, sometimes inadvertently snaring a gorilla. Most trapped gorillas escaped, but not without seriously mutilated limbs that sometimes led to gangrene and death. Poachers who caught gorillas could earn up to $200,000 for one by selling the skeleton to a university and the hands to tourists. From the start, Fossey's mission was to protect the endangered gorillas from extinction—indirectly, by researching and writing about them, and directly, by destroying traps and chastising poachers.

Fossey focused her studies on some 51 gorillas in four family groups. Each group was dominated by a sexually mature silverback, named for the characteristic gray hair on its back. Younger, bachelor males served as guards for the silverback's harem and their juvenile offspring.

When Fossey began observing the reclusive gorillas, she followed the advice of earlier scientists by concealing herself and watching from a distance. But she soon realized that the only way she would be able to observe their behavior as closely as she wanted was by "habituating" the gorillas to her presence. She did so by mimicking their sounds and behavior. She learned to imitate their belches that signal contentment, their barks of curiosity, and a dozen other sounds. To convince them she was their kind, Fossey pretended to munch on the foliage that made up their diet. Her tactics worked. One day early in 1970, Fossey made history when a gorilla she called Peanuts reached out and touched her hand. Fossey called it her most rewarding moment with the gorillas.

She endeared laymen to Peanuts and the other gorillas she studied through her articles in National Geographic magazine. The apes became almost human through her descriptions of their nurturing and playing. Her early articles dispelled the myth that gorillas are vicious. In her 1971 *National Geographic* article she described the giant beasts as ranking among "the gentlest animals, and the shiest." In later articles, Fossey acknowledged a dark side to the gorillas. Six of 38 infants born during a 13-year-period were victims of infanticide. She speculated the practice was a silverback's means of perpetuating his own lineage by killing another male's offspring so he could mate with the victim's mother.

Three years into her study, Fossey realized she would need a doctoral degree to continue receiving support for Karisoke. She temporarily left Africa to enroll at Cambridge University, where she earned her Ph.D. in zoology in 1974. In 1977, Fossey suffered a tragedy that would permanently alter her mission at Karisoke. Digit, a young male she had grown to love, was slaughtered by poachers. Walter Cronkite focused national attention on the gorillas' plight when he reported Digit's death on the CBS Evening News. Interest in gorilla **conservation** surged. Fossey took advantage of that interest by establishing the Digit Fund, a non-profit organization to raise money for anti-poaching patrols and equipment.

Unfortunetly, the money wasn't enough to save the gorillas from poachers. Six months later, a silverback and his mate from one of Fossey's study groups were shot and killed defending their three-year-old son, who had been shot in the shoulder. The juvenile later died from his wounds. It was rumored that the gorilla deaths caused Fossey to suffer a nervous breakdown, although she denied it. What is clear is that the deaths prompted her to step up her fight against the Batusi poachers by terrorizing them and raiding their villages. "She did everything short of murdering those poachers," Mary Smith, senior assistant editor at National Geographic, told contributor Cynthia Washam in an interview. A serious calcium deficiency that causes bones to snap and teeth to rot forced Fossey to leave Africa in 1980. She spent her three-year sojourn as a visiting associate professor at Cornell University. Fossey completed her book, *Gorillas in the Mist,* during her stint at Cornell. It was published in 1983. Although some scientists criticized the book for its abundance of anecdotes and lack of scientific discussion, lay readers and reviewers received it warmly.

When Fossey returned to Karisoke in 1983, her scientific research was virtually abandoned. Funding had run dry. She was operating Karisoke with her own savings. "In the end, she became more of an animal activist than a scientist," Smith said. "Science kind of went out the window."

On Dec. 27, 1985, Fossey, 54, was found murdered in her bedroom at Karisoke, her skull split diagonally from her forehead to the corner of her mouth. Her murder remains a mystery that has prompted much speculation. Rwandan authorities jointly charged American research assistant Wayne McGuire, who discovered Fossey's body, and Emmanuel Rwelekana, a Rwandan tracker Fossey had fired several months earlier. McGuire maintains his innocence. At the urging of U.S. authorities, he left Rwanda before the charges against him were made public. He was convicted in absentia and sentenced to die before a firing squad if he ever returns to Rwanda.

Farley Mowat, the Canadian author of Fossey's biography, *Woman in the Mists,* believes McGuire was a scapegoat. He had no motive for killing her, Mowat wrote, and the evidence against him appeared contrived. Rwelekana's story will never be known. He was found dead after apparently hanging himself a few weeks after he was charged with the murder. Smith, and others, believe Fossey's death came at the hands of a vengeful poacher. "I feel she was killed by a poacher," Smith said. "It definitely wasn't any mysterious plot."

Fossey's final resting place is at Karisoke, surrounded by the remains of Digit and more than a dozen other gorillas she had buried. Her legacy lives on in the Virungas, as her followers have taken up her battle to protect the endangered mountain gorillas. The Dian Fossey Gorilla Fund, formerly the Digit Fund, finances scientific research at Karisoke and employs camp staff, trackers and anti-poaching patrols.

The Rwanda government, which for years had ignored Fossey's pleas to protect its mountain gorillas, on September 27, 1990, recognized her scientific achievement with the Ordre (sic) National des Grandes Lacs, the highest award it has ever given a foreigner. Gorillas in Rwanda are still threatened by cattle ranchers and hunters squeezing in on their **habitat**. According to the Colorado-based Dian Fossey Gorilla Fund, by the early 1990s, fewer than 650 mountain gorillas remained in Rwanda, Zaire, and Uganda. The Virunga Mountains is home to about 320 of them. Smith is among those convinced that the number would be much smaller if not for Fossey's 18 years of dedication to save the great apes. "Her conservation efforts stand above everything else (she accomplished at Karisoke)," Smith said. "She single-handedly saved the mountain gorillas."

Fossil fuels

In early societies, wood or other biological fuels were the main energy source. Today in many non-industrial societies, they continue to be used widely. Biological fuels may be seen as part of a solar economy where energy is extracted from the sun in a way that makes them renewable. However industrialization requires energy sources at much higher density and these have generally been met through the use of fossil fuels such as **coal**, gas, or oil. In the twentieth century a number of other options such as nuclear or higher density **renewable energy** sources (wind power, hydro-electric power, etc.) have also been available. Nevertheless fossil fuels represent the principal source of energy for most of the industrialized world.

Fossil fuels are types of sedimentary organic materials, often loosely called bitumens, with asphalt, a solid, and **petroleum**, the liquid form. More correctly bitumens are sedimentary organic materials that are soluble in **carbon** disulfide. It is this that distinguishes asphalt from coal, which is an organic material largely insoluble in carbon disulfide.

Petroleum can probably be produced from any kind of organism, but the fact that these sedimentary deposits are more frequent in marine sediments has suggested that oils arise from the fats and proteins in material deposited on the sea floor. These fats would be stable enough to survive the initial decay and burial but sufficiently reactive to undergo conversion to petroleum **hydrocarbons** at low temperature. Petroleum consists largely of paraffins or simple alkanes, with smaller amounts of napthenes. There are traces of aromatic compounds such as **benzene** present at the percent level in most crude oils. **Natural gas** is an abundant fossil fuel that consists largely of **methane** and ethane, although traces of higher alkanes are present. In the past, natural gas was regarded very much as a waste product of the petroleum industry and was simply burnt or flared off. Increasingly it is being seen as the favored fuel.

Coal, unlike petroleum, contains only a little **hydrogen**. Fossil evidence shows that coal is mostly derived from the burial of terrestrial vegetation with its high proportion of lignin and cellulose.

Most sediments contain some organic matter, and this can rise to many percent in shales. Here the organic matter can consist of both coals and bitumens. This organic material, often called sapropel, can be distilled to yield petroleum. Oil shales containing the sapropel kerogen are very good sources of petroleum. Shales are considered to have formed where organic matter was deposited along with fine grain sediments, perhaps in fjords, where restricted circulation keeps the oxygen concentrations low enough to prevent decay of the organic material.

Fossil fuels are mined or pumped from geological reservoirs where they have been stored for long periods of time. The more viscous fuels, such as heavy oils, can be quite difficult to extract and refine, which has meant that the latter half of the twentieth century has seen lighter oils being favored. However, in recent decades natural gas has been popular because it is easy to pipe and has a somewhat less damaging impact on the **environment**. These fossil fuel reserves, although large, are limited and non-renewable. The total recoverable light to medium oil reserves are estimated at about 1.6 trillion barrels, of which about a third has already been used. Natural gas reserves are estimated at the equivalent of 1.9 trillion barrels of oil and about a sixth has already been used. Heavy oil and bitumen amount to about 0.6 and 0.34 trillion barrels, most of which has remained unutilized. The gas and lighter oil reserves lie predominantly in the eastern hemisphere, which accounts for the enormous petroleum industries of the Middle East. The heavier oil and bitumen reserves lie mostly in the western hemisphere. These are more costly to use and have been for the most part untapped. Of the 7.6-trillion ton coal reserve, only 2.5% has been used. Almost two thirds of the available coal is shared between China, the former Soviet Union, and the United States.

Petroleum is not burnt in its crude form but must be refined, which is essentially a distillation process that splits the fuel into batches of different volatility. The lighter fuels are used in automobiles, with heavier fuels used as diesel and fuel oils. Modern refining can use chemical techniques in addition to distillation to help make up for changing demands in terms of fuel type and volatility.

The **combustion** of fuels represents an important source of air pollutants. Although the combustion process itself can lead to the production of pollutants such as carbon or **nitrogen oxides**, it has often been the trace impurities in fossil fuels that have been the greatest source of **air pollution**. Natural gas is a much favored fuel because it has only traces of impurities such as hydrogen sulfide. Many of these impurities are removed from the gas by relatively simple scrubbing techniques, before it is distributed. Oil is refined, so although it contains more impurities than natural gas, these become redistributed in the refining process. Sulfur compounds tend to be found only in trace amounts in the light automotive fuels. Thus automobiles are only a minor source of **sulfur dioxide** in the **atmosphere**. Diesel oil can have as much as a percent of sulfur, and heavier fuel oils can have even more, so in some situations these can represent important sources of sulfur dioxide in the atmosphere. Oils also dissolve metals from the rocks in which they are present. Some of the organic compounds in oil have a high affinity for metals, most notably **nickel** and vanadium. Such metals can reach high concentration in oils, and refining will mean that most become concentrated in the heavier fuel oils. Combustion of fuel oil will yield ashes that contain substantial fractions of the trace metals present in the original oil. This means that an element like vanadium is a useful marker of fuel oil combustion.

Coal is often seen as the most polluting fuel because low grade coals can contain large quantities of ash, sulfur, and **chlorine**. However, it should be emphasized that the quantity of impurities in coal can vary widely, depending on where it is mined. The sulfur present in coal is found both as iron pyrites (inorganic) and bound up with organic matter. The **nitrogen** in coal is almost all organic nitrogen. Coal users are often careful to choose a fuel that meets their requirements in terms of the amount of ash, **smoke** or **pollution** risk it imposes. High rank coals such as anthracite have a high carbon content. They are mined in locations such as Pennsylvania and South Wales and contain little volatile matter and burn almost smokelessly. Much of the world's coal reserve is bituminous, which means that it contains about 20–25% volatile matter.

The fuel industry is often seen as responsible for pollutants and environmental risks that go beyond those produced by the combustion of its products. Mining and extraction processes result in **spoil** heaps, huge holes in open cast mining, and the potential for slumping of land (conventional mining). Petroleum refineries are large sources of hydrocarbons, although not usually the largest **anthropogenic** source of volatile organic compounds in the atmosphere. Refineries also release sulfur, carbon, and nitrogen oxides from the fuel that they burn. Liquid natural gas and **oil spills** are experienced both in the refining and transport of petroleum.

Being a solid, coal presents somewhat less risk when being transported, although wind-blown coal dust can cause localized problems. Coal is sometimes converted to coke or other refined products such as Coalite, a smokeless coal. These derivatives are less polluting, although much concern has been expressed about the pollution damage that occurs near the factories that manufacture them. Despite this, the conversion of coal to less polluting synthetic solid, and liquid and gaseous fuels would appear to offer much opportunity for the future.

One of the principal concerns about the current reliance on fossil fuels relates not so much to their limited supply, but more to the fact that combustion releases such large amounts of **carbon dioxide**. Our use of fossil fuels over the last century has increased the concentration of carbon dioxide in the atmosphere. Already there is mounting evidence that this has increased the temperature of the earth through an enhanced **greenhouse effect**.

Fossil water

Water that occurs in an **aquifer** or **zone of saturation** protected or isolated from the current **hydrologic cycle**. This water, because it is old, does not have the levels of **chemicals** or contaminants used in of our industrialized society, and its unblemished **nature** often makes it prized drinking water. In other cases, however, these aquifers are so isolated and the original condition of the water is so high in inorganic salts that scientists have suggested using them for waste disposal or containment areas. *See also* Drinking-water supply; Groundwater; Hazardous waste siting; Water quality

Four Corners

The Hopi believe that the Four Corners—where Colorado, Utah, New Mexico and Arizona meet—is the center of the universe and holds all life on Earth in balance. It also has some of the largest deposits of **coal**, **uranium**, and **oil shale** in the world. According to the **National Academy of Sciences** the Four Corners is a "national sacrifice area." This ancestral home of the Hopi and Dineh (Navajo) people is the center of the most intense energy development in the United States. Traditional grazing and farm land are being swallowed up by uranium mines, coal mines, and **power plants**.

The Four Corners, sometimes referred to as the "joint-use area," is comprised of 1.8 million acres (729,000 ha) of high **desert** plateau where Navajo sheep herders have grazed their flocks on idle Hopi land for generations. In 1972 Congress passed Public Law (PL) 93-531, which established the Navajo/Hopi Relocation Commission who had the power to enforce livestock reduction and the removal of over 10,000 traditional Navajo and Hopi, the largest forced relocation within the United States since the Japanese internment during World War II. Elders of both Nations issued a joint statement that officially opposed the relocation: "The traditional Hopi and Dineh (Navajo) realize that the so-called dispute is used as a disguise to remove both people from the JUA (joint use area), and for non-Indians to develop the land and mineral resources...Both the Hopi and Dineh agree that their ancestors lived in harmony, sharing land and prayers for more than four hundred years...and cooperation between us will remain unchanged."

The traditional Navajo and Hopi leaders have been replaced by Bureau of Indian Affairs (BIA) tribal councils. These councils, in association with the **U.S. Department of the Interior**, Peabody Coal, the Mormon Church, attorneys and public relation firms, created what is commonly known as the "Hopi-Navajo land dispute" to divide the joint-use area, so that the area could be opened up for energy development.

In 1964, 223 Southwest utility companies formed a consortium known as the Western Energy and Supply Transmission Associates (WEST) which includes water and power authorities on the West Coast as well as Four Corners area utility companies. WEST drafted plans for massive coal **surface mining** operations and six coal-fired, electricity-generating plants on Navajo and Hopi land. By 1966 John S. Boyden, attorney for the Bureau of Indian Affairs Hopi Tribal Council, secured lease arrangements with Peabody Coal to surface mine 58,000 acres (23,490 ha) of Hopi land and contracted WEST to build the power plants. This was done despite objections by the traditional Hopi leaders and the self-sufficient Navajo shepherds. Later that same year Kennecott **Copper**, owned in part by the Mormon Church, bought Peabody Coal. Peabody supplies the Four Corners' power plant with coal. The plant burned 5 million tons of coal a year which is the equivalent of ten tons per minute. It emits over 300 tons of **fly ash** and other particles into the San Juan River Valley every day. Since 1968 the coal mining operations and the power plant have extracted over 60 million gal (227 million l) of water a year from the Black Mesa **water table**, which has caused extreme **desertification** of the area, causing the ground in some areas to sink by up to 12 ft (3.6 m).

The worst nuclear accident in American history occurred at Church Rock, New Mexico, on July 26, 1979, when a Kerr-McGee uranium **tailings pond** spilled over into the Rio Puerco. The spill contaminated drinking water from Church Rock to the **Colorado River**, over 200 mi (322 km) to the west. The mill **tailings** dam broke—two months prior to the break cracks in the dam structure were detected yet repairs were never made—and discharged over 100 million gal (379 million l) of highly radioactive water directly into the Rio Puerco River. The main source of potable water for over 1,700 Navahoes was contaminated.

When Kerr-McGee abandoned the Shiprock site in 1980 they left behind 71 acres (29 ha) of "raw" uranium tailings, which retained 85% of the original **radioactivity** of the ore at the mining site. The tailings were at the edge of the San Juan River and have since contaminated communities located downstream.

What is the future of the Four Corners area, with its 100 plus uranium mines, uranium mills, five power plants, depleted **watershed** and radioactive contamination? One "solution" offered by the United States government is to zone the land into uranium mining and milling districts so as to forbid human habitation.

Fox hunting

Fox **hunting** is the sport of mounted riders chasing a wild fox with a pack of hounds. The sport is also known as riding to the hounds, because the fox is pursued by horseback riders following the hounds that chase the fox. The specially trained hounds pursue the fox by following its scent. The riders are called the "field" and their leader is called the "master of the foxhounds.rdquo; A huntsman manages the pack of hounds.

Foxhunting originated in England, and dates back to the Middle Ages. People hunted foxes because they were predators that killed farm animals such as chickens and sheep. Rules were established reserving the hunt to royalty, the aristocracy (people given titles by royalty), and landowners. As the British Empire expanded, the English brought fox hunting to the lands they colonized. The first fox hunt in the United States was held in Maryland in 1650, according to the Masters of Foxhounds Association (MFHA), the organization that controls foxhunting in the United States.

Although the objective of most fox hunts is to kill the fox, some hunts do not involve any killing. In a drag hunt, hounds chase the scent of a fox on a trail prepared before the hunt. In the United States, a hunt ends successfully when the fox goes into a hole in the ground called the "earth."

In Great Britain, a campaign to outlaw fox hunting started in the late twentieth century. The subject drew strong debate on an issue that had not been resolved by March of 2002.

Organized hunt supporters like the Countryside Alliance said a hunting ban would result in the loss of 14,000 jobs. In addition, advocates said that hunts help to eliminate a rural threat by controlling the fox population. Hunt supporters described foxes as vermin, a category of destructive, disease-bearing animals. Hunting was seen as less cruel than other methods of eliminating foxes.

Opponents called foxhunting a "blood sport " that was cruel to animals. According to the International Fund for Animal Welfare (IAFW), more than 15,000 foxes are killed during the 200 hunts held each year. The IAFW reported that young dogs are trained to hunt by pitting them against fox cubs. The group wants the British Parliament to outlaw fox hunting. Drag hunting was suggested as a more humane alternative.

Another opposition group, the Nottingham Hunt Saboteurs Association, attempts to disrupt "blood sports" through "non-violent direct action." Saboteurs' methods include trying to distract hounds by laying false scent trails, shouting, and blowing horns.

Both supporters and opponents of fox hunting claim public support for their positions. In 1997, the issue of a ban was brought to Parliament, the British national legislative body consisting of the House of Lords and the House of Commons. That year, the Labour Party won the general election and proposed a bill to ban hunting with hounds. The following year, the bill passed through some legislative readings. However, time ran out before a final vote was taken.

In July 1999, Prime Minister Tony Blair promised to make fox hunting illegal. That November, Home Secretary Jack Straw called for an inquiry to study the effect of a ban on the rural economy. The Burns Inquiry concluded in June 2000 that a hunting ban would result in the loss of between 6,000 and 8,000 jobs. The inquiry did not find evidence that being chased was painful for foxes. However, the inquiry stated that foxes did not die immediately. This conclusion about a slower, painful death echoed opponents' charges that hunting was a cruel practice.

Two months before the inquiry was released, Straw proposed that lawmakers should have several options to vote on. One choice was a ban on fox hunting; another was to make no changes. A third option was to tighten fox hunting regulations.

In March 2002, Parliament cast non-binding opinion votes on the options. The House of Commons voted for a ban. The House of Lord voted for licensed hunting. After the vote, Rural Affairs Minister Alun Michael said that the government would try to find a common ground before trying to legislate fox hunting. The process of trying to reach agreement was expected to take six months at most.

Fox hunting in other countries

The Scottish Parliament banned hunting in February of 2002. The ban was to take effect on Aug, 1, 2002. The Countryside Alliance announced plans to legally challenge that ruling.

Fox hunting is legal in the following countries: Ireland, Belgium, Portugal, Italy, and Spain. Hunting with hounds is banned in Switzerland. In the United States, the MFHA was established in 1907. In March of 2002, the MFHA reported that there were 171 organized hunt clubs in North America.

Free riders

A free rider, in the broad sense of the term, is anyone who enjoys a benefit provided, probably unwittingly, by others. In the narrow sense, a free rider is someone who receives the benefits of a cooperative venture without contributing to the provision of those benefits. A person who does not participate in a cooperative effort to reduce **air pollution** by driving less, for instance, will still breathe cleaner air—and thus be a free rider—if the effort succeeds.

In this sense, free riders are a major concern of the theory of collective action. As developed by economists and social theorists, this theory rests on a distinction between private and public (or collective) goods. A public good differs from a private good because it is indivisible and nonrival. A public good, such as clean air or national defense, is indivisible because it cannot be divided among people the way food or money can. It is nonrival because one person's enjoyment of the good does not diminish anyone else's enjoyment of it. Smith and Jones may be rivals in their desire to win a prize, but they cannot be rivals in their desire to breathe clean air, for Smith's breathing clean air will not deprive Jones of an equal chance to do the same.

Problems arise when a public good requires the cooperation of many people, as in a campaign to reduce **pollution** or conserve resources. In such cases, individuals have little reason to cooperate, especially when cooperation is burdensome. After all, one person's contribution—using less **gasoline** or electricity, for example—will make no real difference to the success or failure of the campaign, but it will be a hardship for that person. So the rational course of action is to try to be a free rider who enjoys the benefits of the cooperative effort without bearing its burdens. If everybody tries to be a free rider, however, no one will cooperate and the public good will not be provided. If people are to prevent this from happening, some way of providing selective or individual incentives must be found, either by rewarding people for cooperating or punishing them for failing to cooperate.

The free rider problem posed by public goods helps to illuminate many social and political difficulties, not the least of which are environmental concerns. It may explain why voluntary campaigns to reduce driving and to cut energy use so often fail, for example. As formulated in Garrett Hardin's **Tragedy of the Commons**, moreover, collective action theory accounts for the tendency to use common resources—grazing land, fishing banks, perhaps the earth itself—beyond their **carrying capacity**. The solution, as Hardin puts it, is "mutual coercion, mutually agreed upon" to prevent the overuse and destruction of vital resources. Without such action, the desire to ride free may lead to irreparable ecological damage.

Freon

The generic name for several **chlorofluorocarbons** (CFCs) widely used in refrigerators and air conditioners, including the systems in houses and cars. Freon—comprised of **chlorine**, fluorine, and **carbon** atoms—is a non-toxic gas at room temperature. It is environmentally significant because it is extremely long-lived in the **atmosphere**, with a typical **residence time** of 70 years. This long life-span permits CFCs to disperse, ultimately reaching the **stratosphere** 19 mi (30 km) above the earth's surface. Here, high energy photons in sunlight break down freon, and chlorine atoms liberated during this process participate in other chemical reactions that consume **ozone**. The final result is to decrease the stratospheric ozone layer that shields the earth from damaging **ultraviolet radiation**. Under the 1987 Montreal Protocol, 31 industrialized countries agreed to phase out CFC freon production. Freon substitutes use **bromine** atoms to replace the chlorine atoms, providing a substitute refrigeration compound that appears less damaging, although considerably more expensive and less energy efficient.

Fresh water ecology

The study of fresh water habitats is called **limnology**, coming from the Greek word *limnos*, meaning "pool, lake, or swamp." Fresh water habitats are normally divided into two groups: the study of standing bodies of water such as lakes and ponds (called lentic ecosystems) and the study of rivers, streams, and other moving sources of water (called lotic ecosystems). Another important area that should be included is fresh water **wetlands**.

The historical roots of limnology go back to F. A. Forel, who studied Lake Geneva, Switzerland, in the late 1800s and E. A. Birge and C. Juday, who studied lakes in Wisconsin in the early 1900s. More recently, the modern "father" of limnology can arguably be attributed to G. Evelyn Hutchinson, who died in 1991 after teaching at Yale University for more than 40 years. Among his prolific writings are four treatises on limnology which offer the most detailed descriptions of lakes that have been published.

Fresh water **ecology** is an intriguing field because of the great diversity of aquatic habitats. For example, lakes can be formed in different ways: volcanic origin such as Crater Lake, Oregon; tectonic (earth movement) origin like **Lake Tahoe** in California/Nevada and **Lake Baikal** in Siberia; glacially-derived lakes like the **Great Lakes** or smaller kettle hole or cirque lakes; oxbow lakes which form as rivers change their meandering paths; and human-created reservoirs. Aquatic habitats are strongly influenced by the surrounding **watershed**, and lakes in the same geographic area tend to be of the same origin and have similar **water quality**.

Lakes are characteristically non-homogeneous. Physical, chemical, and biological factors contribute to both horizontal and vertical zonations. For example, light penetration creates an upper photic (lighted) zone and a deeper aphotic (unlit) zone. **Phytoplankton** (microscopic algae such as diatoms, desmids, and filamentous algae) inhabit the **photic zone** and produce oxygen through **photosynthesis**. This creates an upper productive area called the trophogenic (productive) zone. The deeper area where **respiration** prevails is called the tropholytic (unproductive) zone. **Zooplankton** (microscopic invertebrates such as cladocerans, copepods, and rotifers) and **nekton** (free-swimming animals such as fish) inhabit both of these zones. The boundary area where oxygen produced from photosynthesis equals that consumed through respiration is called the compensation depth. Nearshore areas where light penetrates to the bottom and aquatic macrophytes such as cattails and bulrushes grow, are called the **littoral zone**. This is typically the most productive area, and it is more pronounced in ponds than in lakes. Open water areas are called the limnetic zone, where most **plankton** inhabit. Some **species** of zooplankton are found more concentrated in deeper waters during the day and in greater numbers in the upper waters during the night. One explanation for this vertical **migration** is that these zooplankton, often large and sometimes pigmented, are avoiding visually-feeding planktivorous fish. These zooplankton are thus able to feed on phytoplankton in the trophogenic zone during periods of darkness, and then swim to deeper waters during daylight hours. Phytoplankton are also adapted for existence in the limnetic zone. Some species are quite small in size (less than 20 microns in diameter and called nannoplankton), allowing them to be competitive at **nutrient** uptake due to their high surface-to-volume ratio. Other groups form large colonies, often with spines, lessening the negative impacts of herbivory and sinking. Blue-green algae produce oils that help them float on or near the water's surface. Some are able to fix atmospheric **nitrogen** (called **nitrogen fixation**), giving them a competitive advantage in low-nitrogen conditions. Other species of blue-greens produce toxic **chemicals**, making them inedible to herbivores. There have even been reports of cattle deaths following ingestion of water with dense growths of these algae.

Lakes can be isothermal (uniform temperature from top to bottom) during some times of the year, but during the summer months they are typically thermally stratified with an upper, warm layer called the epilimnion (upper lake), and a colder, deeper layer called the hypolimnion (lower

lake). These zones are separated by the metalimnion, which is determined by the depths with a temperature change of more than 1°C per meter depth, called the **thermocline**. The summer temperature **stratification** creates a density gradient that effectively prevents mixing between zones.

Wind is another physical factor that influences aquatic habitats, particularly in lakes with broad surface areas exposed to the main direction of the wind, called fetch. Strong winds can produce internal standing waves called seiches that create a rocking motion in the water once the wind dies down. Other types of wind-generated water movements include Ekman spirals and Langmuir cells. Deep or chemically-stratified lakes that never completely mix are called meromictic. Lakes in tropical regions that mix several times a year are called polymictic. In regions with severe winters resulting in ice covering the surface of the lake, mixing normally occurs only during the spring and fall when the water is isothermal. These lakes are called dimictic, and the mixing process is called overturn. People living downwind of these lakes often notice a rotten egg smell caused by the release of **hydrogen** sulfide. This gas is a product of benthic (bottom-dwelling) bacteria that inhabit the **anaerobic** muds of productive lakes (discussed below in more detail).

Lakes that receive a low-nutrient input remain fairly unproductive, and are called **oligotrophic** (low nourished). These lakes typically have low concentrations of phytoplankton, with diatoms being the main representative. Moderately productive lakes are called mesotrophic. Eutrophic (well nourished) lakes receive more nutrient input and are therefore more productive. They are typically shallower than oligotrophic lakes and have more accumulated bottom sediments that often experience summer anoxia. These lakes have an abundance of algae, particularly blue-greens (Cynaobacteria) which are often considered nuisance algae because they float on the surface and out-compete the other algae for nutrients and light.

Most lakes naturally age and become more productive over time; however, large, deep lakes may remain oligotrophic. The maturing process is called eutrophication and it is regulated by the input of nutrients which are needed by the algae for growth. Definitive limnological studies done in the 1970s concluded that **phosphorus** is the key limiting nutrient in most lakes. Thus, the accelerated input of this chemical into streams, rivers, and eventually lakes by excess fertilization, sewage input (both human and animal), and **erosion** is called **cultural eutrophication**. Much debate and research has been spent on how to slow down or control this process. One interesting management tool is called biomanipulation, in which piscivorous (fish-eating) fish are added to lakes to consume planktivorous (plankton-eating) fish. Because the planktivores are visual feeders on the largest prey, this allows higher numbers of large zooplankton to thrive in the water, which consume more phytoplankton, particularly non-toxic blue-green algae. A more practical approach to controlling cultural eutrophication is by limiting the nutrient **loading** into our bodies of water. Although this isn't easy, we must consider ways of limiting excessive uses of fertilizers, both at home and on farms, as well as more effectively regulating the release of treated sewage into rivers and lakes, particularly those which are vulnerable to eutrophication. Another lake management tool is to aerate the bottom (hypolimnetic) water so that it remains oxygenated. This keeps iron in the oxidized state (Fe^{+3}), which chemically binds with phosphate (PO_4) and prevents it from being available for algal uptake. Lakes that have anoxic bottom water keep iron in the reduced state (Fe^{+2}), and phosphate is released from the **sediment** into the water. Fall and spring turnover then returns this limiting nutrient to the photic zone, promoting high algal growth. When these organisms eventually die and sink to the bottom, **decomposers** use up more oxygen, and we get a "snow ball" effect. Thus, productive lakes can become more eutrophic with time, and may eventually develop into hypertrophic (overly productive) systems.

Lotic ecosystems differ from lakes and ponds in that currents are more of a factor and primary production inputs are generally external (allochthonous) instead of internal (autochthonous). Thus, a river or stream is considered a heterotrophic **ecosystem** along most of its length. Gradients in physical and chemical parameters also tend to be more horizontal than vertical in running water habitats and organisms living in lotic ecosystems are specially adapted for surviving in these conditions. For example, trout require higher amounts of **dissolved oxygen**, and are primarily found in relatively cold, fast-moving water with low nutrient input. Carp are able to tolerate warmer, slower, more productive bodies of running water. Darters are fish that quickly dart back and forth behind rocks in the bottom of fast-moving streams and rivers as they feed on aquatic insects. Many of these insects are shredders and **detritivores** on the organic material like leaves that enter the water. Other groups specialize by scraping algae and bacteria off rocks in the water.

Recently, ecologists have begun to take a greater interest in studying fresh water wetlands. These areas are defined as being inundated or saturated by surface or ground water for most of the year, and therefore having characteristic wetland vegetation. Although some people consider these areas a nuisance and prefer them being drained, ecologists realize that they are valuable habitats for migrating water fowl. They also serve as major "adsorptive" areas for nutrients, which are particularly useful around sewage lagoons. We must therefore take greater care in preserving these habitats.

Friends of the Earth

Friends of the Earth (FOE) is a public interest environmental group committed to the **conservation**, restoration, and rational use of the **environment**. Founded by David Brower and other militant environmentalists in San Francisco in 1969, FOE works on the local, national, and international levels to prevent and reverse **environmental degradation**, and to promote the wise use of **natural resources**.

FOE has an international membership of one million. Its particular areas of interest include **ozone layer depletion**, **greenhouse effect**, toxic chemical safety, **coal** mining, coastal and ocean **pollution**, the destruction of tropical forests, **groundwater** contamination, corporate accountability, and **nuclear weapons** production. In addition to its efforts to influence policy and increase public awareness of environmental issues, FOE's ongoing activities include the operation of the Take Back the Coast Project and the administration of the Oceanic Society. Over the years, FOE has published numerous books and reports on various topics of concern to environmentalists.

FOE was originally organized to operate internationally and now has national organizations in some 63 countries. In several of these, most notably the United Kingdom, FOE is considered to be the best-known and most effective **public interest group** concerned with environmental issues.

The organization has changed its strategies considerably over the years, and not without considerable controversy within its own ranks. Under Brower's leadership, FOE's tactics were media-oriented and often confrontational, sometimes taking the form of direct political protests, boycotts, sit-ins, marches, and demonstrations. Taking a **holistic approach** to the environment, the group argued that fundamental social change was required for lasting solutions to many environmental problems.

FOE eventually moved away from confrontational tactics and towards a new emphasis on lobbying and legislation, which helped provoke the departure of Brower and some of the group's more radical members. FOE began downplaying several of its more controversial stances (for example, on the control of nuclear weapons) and moved its headquarters from San Francisco to Washington, D.C. More recent controversies have concerned FOE's endorsement of so-called **green products** and its acceptance of corporate financial contributions.

FOE remains committed, however, to most of its original goals, even if it has foresworn its earlier illegal and disruptive tactics. Relying more on the technical competence of its staff and the technical rationality of its arguments than on idealism, FOE has been highly successful in influencing legislation and in creating networks of environmental, consumer, and human rights organizations worldwide. Its publications and educational campaigns have been quite effective in raising public consciousness of many of the issues with which FOE is concerned.

Frogs

Frogs are amphibians belonging to the order anura. The anuran group has nearly 2,700 **species** throughout the world and includes both frogs and toads. The word *anura* means "without a tail," and the term applies to most adult frogs. The anura are distinguished from tailed amphibians (urodeles) such as salamanders because the latter retain a tail as an adult.

One of the most studied and best understood frogs is the northern leopard frog, *Rana pipiens*. This species is well-known to most children, to people who love the outdoors, and to scientists. Leopard frogs live throughout much of the United States as well as Canada and northern Mexico. Inhabiting a diverse array of environmental conditions, the order anura exhibits an impressive display of anatomical and behavioral variations among its members. Despite such diversity, the leopard frog is often used as a model that represents all members of the group.

Leopard frogs mate in the early spring. The frogs deposit their eggs in jelly-like masses. These soft formless clumps may be seen in temporary ponds where frogs are common. Early embryonic development occurs within the jelly mass after which the eggs hatch releasing small swimming tadpoles. The tadpoles feed on algal periphyton, fine organic **detritus**, and yolk reserves through much of the spring and early summer. Next, metamorphosis begins a few weeks or up to two years after the eggs is hatched depending

of the species. Metamorphosis is the process whereby amphibious tadpoles lose their gills and tails and develop arms and legs. The process of metamorphosis is complex and involves not only the loss of the tail and the development of limbs, but also a fundamental reorganization of the gut. For example, in the leopard frog, the relatively long intestine of the vegetarian tadpole is reorganized to form the short intestine of the carnivorous adult frog because nutrients are more difficult to extract from plant sources. Additionally, metamorphosis profoundly changes the method of **respiration** in the leopard frog. As the animal loses it gills, air-breathing lungs are formed and become functional. A significant portion of respiration and gas exchange will occur through the skin of the adult frog. When metamorphosis of a tadpole is complete, the result is a terrestrial, insect-eating, air-breathing frog.

Frogs are important tolls for biological learning and research. Many students first encounter vertebrate anatomy with the dissection of an adult leopard frog. Consequently physiologists have used frogs for the study of muscle contraction and the circulation of blood which is easily seen in the webbing between the toes of a frog. Embryologists have used frogs for study because they lay an abundance of eggs. A mature *R. pipiens* female may release 3,000 or more eggs during a single spawning. Frog eggs are relatively large and abundant which simplifies manipulation and experimentation. Another anuran, the South African clawed frog, *Xenopus laevis*, is useful in research because it can be cultivated to metamorphosis easily and can be bred any time of year. For these reasons, frogs emerge as extremely useful laboratory test animals that provide valuable information about human biology.

Frogs and biomedical research

Many biological discoveries have been made or enhanced by using frogs. For example, the role of sperm in development was studied in the late 1700s in frogs. Amphibians in general, including frogs, have significantly more deoxyribonucleic **acid** (DNA) per cell than do other chordates. Thus, their chromosomes are large and easy to see with a microscope. In addition, induced ovulation in frogs by pituitary injection was developed during the early 1930s. Early endocrinologists studied the role of the hormone thyroxine (also found in human beings) in vertebrate development in 1912. The role of viruses in animal and human **cancer** is receiving renewed interest—the first herpes **virus** known to cause a cancer was the frog cancer herpes virus. Furthermore, mammalian and human **cloning**, a controversial topic, has its foundations in the cloning of frogs. The first vertebrate ever cloned was *Rana pipiens*, in an experiment published by Thomas King and Robert Briggs in 1952. As such, experimentation with frogs has contributed greatly to biomedical research.

Unfortunately, the future of amphibians, like the northern leopard frog, appears to be jeopardized. Most amphibians in the world are frogs and toads. Since the 1980s, scientists have noted a distinct decline in amphibian populations. Worldwide, over 200 species of amphibians have experienced recent population declines. At least 32 documented species extinctions have occurred. Of the 242 native North American amphibian species, the U.S. Nature Conservancy has identified three species that are presumed to be extinct, another three classified as possibly extinct, with an additional 38% categorized as vulnerable to **extinction**. According to the United States **Fish and Wildlife Service**, there are four frog species listed as endangered and three listed as threatened.

The actual cause of the reductions in frog and amphibian populations remains unclear, but many well-supported hypotheses exist. One speculation is the run-off of **chemicals** that poison ponds producing defective frogs that cannot survive well. A second possibility is an increase in amphibian disease caused by virulent pathogens. Viral and fungal infection of frogs has led to recent declines in many populations. A third explanation involves parasitic infections of frogs with flatworms, causing decreased survival. Another theory blames atmospheric **ozone** depletion for frog decline. Yet another implicates a toxic combination of intensified agriculture, **drainage** of **habitat**, and predator changes as the cause for the drastic declines in frog populations. While each argument has merits of its own, it is unlikely that any single cause can adequately explain all amphibian decline.

The poisoned pond hypothesis brought the issue of frog population decline to the forefront. Several years ago, students on a field trip at a pond near the Minnesota community of Henderson discovered a number of frogs with extremely abnormal limbs. Some frogs had three or more hind legs, some had fused appendages, and some had no legs at all. Concerned with what they had found, their teacher, Cindy Reinitz, and her students contacted the Minnesota **Pollution Control** Agency. Soon, state agency biologists and officials from the University of Minnesota confirmed the presence of many abnormal frogs at the site. The word spread, and by late 1996, many sites in Minnesota were known to have abnormal frogs.

Frog developmental abnormalities are not new to science. What made the Minnesota case of frog malformations different, however, was the extraordinary concentration of abnormal frogs in an unusually large number of locations. Concern became more urgent when abnormal animals also were reported in several other states, then Canada, and finally in Japan. Many of the abnormal frogs were found in agricultural areas where large amounts of fertilizers and pesticides were used.

One reason for concern is that frogs and humans metabolize toxic **xenobiotic** chemicals, such as fertilizers or pesticides, in similar ways. Also, human beings and frogs have very similar early developmental stages, which is why frogs are used as model animals in embryology. Because of this, worry exists regarding the potential for human developmental abnormalities from such chemicals. Some of the chemicals implicated in the frog malformations were retinoids. Retinoids are derivatives of vitamin A that are potent and crucial hormonal regulators of vertebrate embryological development. Numerous laboratory studies using retinoic acid (a form of retinoid) have reproduced the abnormalities seen in the Minnesota frogs, and the role of retinoids in the regulation of genes involved in limb development is well-characterized. Frog anatomical defects are regarded as a warning sign for potential problems in humans exposed to the same chemicals, since retinoic acid regulates human limb development as well.

Disease is a growing problem for frogs. Recently, two important frog pathogens have been identified and are suspected to play a role in global frog decline. Iridiovirus, a virus that commonly infects fish and insects, has now been found to infect frogs. An aquatic fungus, chytrid, is also implicated in frog decline. Infection with the fungus is called chytridiomycosis. The chytrid fungus, *Batrachochytrium dendrobatidis*, which normally resides in decaying plant material, causes the degeneration of tadpole mouthparts. This results in the death of post-metamorphic frogs, and is reportedly involved in amphibian decline in **Australia**, Europe, and recently in the Sierra Nevada region of California. In Australia the depletion of the frog population may have been caused by a disease introduced through infected fish. The Australian cane toad, *Bufo marinus*, may be responsible for spreading a virus to other frogs outside its native range.

Another potential cause for the striking decline of frog populations involves parasitism, the act of being a parasite. Parasitism is a type of **symbiosis** in which a parasitic organism gains benefit from living within or upon a host organism. The host, in turn, gains no benefit, and in fact may be harmed by the symbiosis. Scientists have discovered that a parasitic trematode or flatworm is threatening many frog populations. Trematode larvae erupt from snails inhabiting ponds, which then infect frog tadpoles. Once inside the tadpoles, the flatworm larvae multiply and physically scramble developing limb bud cells in the hind quarters of the tadpole. If the limb bud cells are not in their proper places, malformations are the consequence. The result of such parasitism by flatworms is adult frogs with multiple legs or fused legs. It is believed that the flatworms derive benefit from the relationship because frogs with defective legs are easier for birds to prey upon. Birds that eat infected frogs in-turn become infected. The cycle is complete when bird droppings littered with flatworm larvae are dropped into pond water.

A fourth possible explanation for the decline of frogs involves ozone depletion. Some scientists believe that atmospheric ozone loss has led to an increase in ultraviolet light penetration to the surface of the earth. Frogs are exquisitely sensitive to ultraviolet light. It is believed that due to increased UV-B penetration, mutations in frogs has been increased, resulting in limb malformations. Evidence for this hypothesis exists in laboratory experiments that have been able to reliably replicate the limb malformations observed in the Minnesota ponds using UV-B radiation on experimental frogs.

Many scientists believe, however, that multiple factors are to blame for frog decline. They believe that synergy, or the combination of many factors is the most plausible explanation for the decrease in the number and diversity of frogs. **Climate** change, urbanization, prolonged **drought**, global warming, secondary **succession**, drainage of habitat for housing developments, **habitat fragmentation**, introduced predators, loss of territory, and the aforementioned infectious and **poisoning** reasons may all simultaneously contribute to the decline of frog populations worldwide. Humans perpetuate the decline by **hunting** frogs for food. Because the decrease in numbers and diversity of frogs is so striking, conservationists are concerned that it is an early indicator of the consequences of human progress and overpopulation.

Frontier economy

An economy similar to that which was prevalent at the "frontier" of European settlement in North America in the eighteenth and nineteenth centuries. A frontier economy is characterized by relative scarcities (and high prices) of capital equipment and skilled labor, and by a relative abundance (and low prices) of **natural resources**. Because of these factors, producers will look to utilize natural resources instead of capital and skilled labor whenever possible. For example, a sawmill might use a blade that creates large amounts of wood waste since the cost of extra logs is less than the cost of a better blade. The long-term environmental effects of high natural resource use and **pollution** from wastes are ignored since they seem insignificant compared to the vastness of the natural resource base.

A frontier economy is sometimes contrasted with a spaceship economy, in which resources are seen as strictly limited and need to be endlessly recycled from waste products.

Frost heaving

The lifting of earth by **soil** water as it freezes. Freezing water expands by approximately nine percent and exerts a pressure of about fifteen tons per square inch. Although this pressure and accompanying expansion are exerted equally in all directions, movement takes place in the direction of least **resistance**, namely upward. As a result, buried rocks, varying from pebbles to boulders, can be raised to the ground surface; small mounds and layers of soil can be heaved up; young plants can be ripped from the earth or torn apart below ground; and pavement and foundations can be cracked and lifted. Newly planted tree seedlings, grass, and agricultural crops are particularly vulnerable to being lifted by acicular ice crystals during early fall and late spring frosts. Extreme cases in cold climates at high latitudes or high elevation at mid-latitudes result in characteristic patterned ground.

Fuel cells

Fuel cells produce energy through electrochemical reactions rather than through the process of **combustion**. They convert **hydrogen** and oxygen into electricity and heat. Fuel cells are sometimes compared to batteries because, like batteries, they have two electrodes, an anode and a cathode, through which an electrical current flows into and out of the cell. But fuel cells are fundamentally different electrical devices from batteries since the latter simply store electrical energy, while the former are a source of electrical energy.

In a fuel cell, chemical energy is converted directly into electrical energy by means of an oxidation-reduction reaction. The British physicist Sir William Grove developed the fuel cell concept in 1839. A practical, working model of the concept was not constructed until a century later, however. The earliest fuel cells carried out this energy conversion by means of the reaction between hydrogen gas and oxygen gas, and formed water as a by-product. In this chemical reaction, each hydrogen atom loses one electron to an oxygen atom. The exchange of electrons, from hydrogen to oxygen, is what characterizes an oxidation-reduction reaction. A fuel cell thus creates a pathway through which electrons lost by hydrogen atoms must flow before they reach oxygen atoms. The cell typically consists of four basic parts: an anode, a cathode, an electrolyte, and an external circuit.

In the simplest fuel cell, hydrogen gas is pumped into one side of the fuel cell where it passes into a hollow, porous anode. At the anode, hydrogen atoms lose an electron to hydroxide ions present in the electrolyte. The source hydroxide ions is a solution of potassium hydroxide in water. The electrons released in this reaction travel up the anode, out of the fuel cell, and into the external circuit, which carries the flow of electrons (an electric current) to some device such as a light bulb where it can be used. Meanwhile, a second reaction is taking place at the opposite pole of the fuel cell. Oxygen gas is pumped into this side of the fuel cell where it passes into the hollow, porous cathode. Oxygen atoms pick up electrons from the cathode and react with water in the electrolyte to regenerate hydroxide ions.

As a result of the two chemical reactions taking place at the two poles of the fuel cell, electrons are removed from hydroxide ions at the anode, passed through the external circuit where they can be used to do work, returned to the cell through the cathode, and then returned to water molecules in the electrolyte. Meanwhile, oxygen and hydrogen are used up in the production of water. A fuel cell such as the one described here should have a voltage of 1.23 volts and a theoretical efficiency (based on the heat of combustion of water) of 83%. The actual voltage of a typical hydrogen/oxygen fuel cell normally ranges between 0.6 to 1.1 volts depending on operating conditions.

Fuel cells have many advantages as energy sources. They are significantly more efficient than energy sources such as nuclear or fossil-fueled **power plants**. In addition, a fuel cell is technically simple and lightweight. Also, the product of the fuel cell reaction —water— is of course harmless to humans and the rest of the **environment**. Finally,

both hydrogen and oxygen, the raw materials used in a fuel cell, are abundant in **nature**. They can both be obtained from water, the most common single compound on the planet.

Until recently, electricity produced from fuel cells was more expensive than that obtained from other sources, and they have been used in only specialized applications. One of these is in spacecrafts, where their light weight represents an important advantage. For example, the fuel cell used on an 11-day Apollo moon flight, weighed 500 lb (227 kg), while a conventional generator would have weighed several tons. In addition, the water produced in the cell was purified and then used for drinking.

A great many variations on the simple hydrogen/oxygen fuel cell have been investigated. In theory, any fuel that contains hydrogen can be used at the anode, while any **oxidizing agent** can be used at the cathode. Elemental hydrogen and oxygen are only the simplest, most fundamental examples of each.

Among the hydrogen-containing compounds explored as possible fuels are hydrazine, **methanol**, ammonia, and a variety of **hydrocarbons**. The order in which these fuels are listed here corresponds to the efficiency with which they react in a fuel cell, with hydrazine being most reactive (after hydrogen itself) and the hydrocarbons being least reactive. Each of these potential alternatives has serious disadvantages. Hydrazine, for example, is expensive to manufacture and dangerous to work with.

In addition to oxygen, liquid oxidants such as hydrogen peroxide and nitric **acid** have also been investigated as possible cathode reactants. Again, neither compound works as efficiently as oxygen itself, and each presents problems of its own as a working fluid in a fuel cell.

The details of fuel cell construction often differ depending on the specific use of the cell. Cells used in spacecraft, for example, use cathodes made of **nickel** oxide or gold and anodes made of a platinum alloy. The hydrogen and oxygen used in such cells are supplied in liquid form that must be maintained at high pressure and very low temperature.

Fuel cells can also operate with an acidic electrolyte such as phosphoric or a fluorinated sulfuric acid. The chemical reactions that occur in such a cell are different from those described for the alkaline (potassium hydroxide) cell described above. Fuel cells of the acidic type are more commonly used in industrial applications. They operate at a higher temperature than alkaline cells, with slightly less efficiency.

Another type of fuel cell makes use of a molten salt instead of a water solution as the electrolyte. In a typical cell of this kind, hydrogen is supplied at the anode of the cell, **carbon dioxide** is supplied at the cathode, and molten potassium carbonate is used as the electrolyte. In such a cell, the fundamental process is the same as in an aqueous electrolyte cell. Electrons are released at the anode. The electrons then travel through the external circuit where they can do work. They return to the cell through the cathode where they make the cathodic reaction possible.

Yet a third type of fuel cell is now being explored, one that makes use of state-of-the-art and sometimes exotic solid-state technology. This is the high- temperature solid ionic cell. In one design of this cell, the anode is made of nickel metal combined with zirconium oxide while the cathode is composed of a lanthanum-manganese alloy doped with strontium. The electrolyte in the cell is a mixed oxide of yttrium and zirconium. The fuel provided to the cell is **carbon monoxide** or hydrogen, either of which is oxidized by the oxygen in ordinary air. A series of these cells are connected to each other by connections made of lanthanum chromite doped with magnesium metal.

The solid ionic cell is particularly attractive to **electric utilities** and other industries because it contains no liquid, as the other fuel cell designs do. The presence of such liquids creates problems in the handling and maintenance of conventional fuel cells that are eliminated with the all-solid cell.

The Proton Exchange Membrane (PEM) fuel cell and Direct Methanol Fuel cells (DMFC) are similar in that they both use a polymer membrane as the electrolyte, but a DMFC has an anode catalyst that utilizes hydrogen from liquid methanol, rather than from hydrogen gas. This improvement avoids the storage problems that are inherent with the use of hydrogen gas. Other possibilities are made up of stacks of fuel cells that use PEM-type technology. In 2001, the **U.S. Department of Energy** started a new program designed to implement the development of efficient and low-cost versions of these “planar solid-oxide fuel cells", or SOFCs.

Some experts are enthusiastic about the future role of fuel cells in the world’s energy equation. If costs for all these emerging technologies can be reduced, their high efficiency should make them attractive alternatives to fossil fuel- and nuclear-generated electricity. The major concerns about fuel cell technologies include the inability of fuel cells to store power and the associated requirement that energy be generated on an “as needed” basis. Proposals have been made to use pumped water, compressed air, and batteries to store energy that is generated when times of demand are low.

For that reason, still more variations in the fuel cell are being explored. One of the most intriguing of these future possibilities is a cell no more than 0.04–0.07 in (1–2 mm) in diameter. These cells have the advantage of a greater electrode surface area on which oxidation and reduction occur than do conventional cells. The distance that electrons have to travel in such cells is also much shorter,

resulting in their having a greater power output per unit volume than that of conventional cells. The technology for constructing and maintaining such small cells is not, however, fully developed. Because of more stringent clean air standards, the **transportation** industry is especially interested in increasing **energy efficiency** of the **automobile** industry. The utility of **hybrid vehicles** that use conventional fuels when accelerating and fuel cells for highway driving is being investigated. These cars would use **gasoline** or methanol as a fuel source for both the conventional engine and as a source of hydrogen for the fuel cells. Fuel cells are also being researched for the aviation industry. An innovative approach is to couple photovoltaic or solar cell technology with fuel cell technology to provide a source of energy for the plane that could be used day or night.

Fuel switching

Fuel switching is the substitution of one energy source for another in order to meet requirements for heat, power, and/or electrical generation. Generally, this term refers to the practices of some industries that can substitute among **natural gas**, electricity, **coal**, and LPG within 30 days without modifying their fuel-consuming equipment and that can resume the same level of production following the change. The **U.S. Department of Energy** estimates that among manufacturers in 1991, 2.8 quadrillion Btus of energy consumption could be switched from a total consumption of about 20.3 quadrillion Btus, representing about 14%. Price is the primary reason for fuel switching; however, additional factors may include environmental regulations, agreements with energy or fuel suppliers, and equipment capabilities.

Fugitive emissions

Contaminants that enter the air without going through a smokestack and, thus, are often not subject to control by conventional **emission** control equipment or techniques. Most fugitive emissions are caused by activities involving the production of dust, such as **soil erosion** and **strip mining**, or building demolition, or the use of volatile compounds. In a steel-making complex, for example, there are several identifiable smokestacks from which emissions come, but there are also numerous sources of fugitive emissions, which escape into the air as a result of processes such as producing coke, for which there is no identifiable smokestack. The control of fugitive emissions is generally much more complicated and costly than the control of smokestack emissions for which known add-on technologies to the smokestack have been developed. Baghouses and other costly mechanisms typically are needed to control fugitive emissions.

Fumigation

Most commonly, fumigation refers to the process of disinfecting a material or an area by using some type of toxic material in gaseous form. The term has a more specialized meaning in **environmental science**, where it refers to the process by which pollutants are mixed in the **atmosphere**. Under certain conditions, emitted pollutants rise above a stable layer of air near the ground. These pollutants remain aloft until convective currents develop, often in the morning, at which time the cooler pollutants "trade places" with air at ground level as it is warmed by the sun and rises. The resulting damage to ecosystems from the pollutants is most obvious around metal smelters.

Fund for Animals

Founded in 1967 by author and humorist **Cleveland Amory**, the Fund is one of the most activist of the national animal protection groups. Formed "to speak for those who can't," it has led sometimes militant campaigns against sport **hunting**, **trapping**, and wearing furs, as well as the killing of **whales**, **seals**, bears, and other creatures. Amory, in particular, has campaigned tirelessly against these activities on television and radio, and in lectures, articles, and books.

In the early 1970s, the Fund worked effectively to rally public opinion in favor of passage of the Marine Mammal Protection Act, which was signed into law in October 1972. This act provides strong protection to whales, **seals and sea lions**, **dolphins**, sea otters, polar bears, and other ocean mammals. In 1978, the Fund bought a British trawler and renamed it *Sea Shepherd*. Under the direction of its captain,

Paul Watson, they used the ship to interfere with the baby seal kill on the ice floes off Canada. Activists sprayed some 1,000 baby harp seals with a harmless dye that destroyed the commercial value of their white coats as fur, and the ensuing publicity helped generate worldwide to the seal kill and a ban on imports into Europe. In 1979, *Sea Shepherd* hunted down and rammed *Sierra*, an outlaw **whaling** vessel that was illegally killing protected and **endangered species** of whales. After *Sea Shepherd* was seized by Portuguese authorities, Watson and his crew scuttled the ship to prevent it from being given to the owners of *Sierra* for use as a whaler.

Also in 1979, the Fund used helicopters to airlift from the Grand Canyon almost 600 wild burros that were scheduled to be shot by the **National Park Service**. The airlift was so successful, and generated so much favorable publicity, that it led to similar rescues of feral animals on public lands that the government wanted removed to prevent damage to vegetation. Burros were also airlifted by the Fund from Death Valley National Monument, as were some 3,000 wild goats on San Clemente Island, off the coast of California, scheduled to be shot by the United States Navy.

Many of the wild horses, burros, goats, and other animals rescued by the Fund end up, at least temporarily before adoption, at Black Beauty Ranch, a 1430-acre (578-ha) sanctuary near Arlington, Texas. The ranch has provided a home for abused race and show horses, a non-performing elephant, and Nim, the famous signing chimpanzee who was saved from a medical laboratory.

Legal action initiated by the Fund has resulted in the addition of almost 200 **species** to the U.S. Department of the Interior's list of threatened and endangered species, including the **grizzly bear**, the Mexican wolf, the Asian elephant, and several species of kangaroos. The Fund is also active on the grassroots level, working on measures to restrict **hunting and trapping**. A recent example is the passage of an initiative in Colorado in November 1992 banning the use of dogs and bait to hunt bears, and halting the spring bear hunt, when mothers are still nursing their cubs.

Fungi

Fungi are one of the five Phyla of organisms. Fungi are broadly characterized by cells that possess nuclei and rigid cell walls but lack chlorophyll. Fungal spores germinate and grow slender tube-like structures called *hyphae*, separated by cell walls called *septae*. The vegetative **biomass** of most fungi in **nature** consists of masses of hyphae, or *mycelia*. Most **species** of fungi inhabit **soil**, where they are active in the **decomposition** of organic matter. The biologically most complex fungi periodically form spore-producing fruiting structures, known as mushrooms. Some fungi occur in close associations, known as *mycorrhizae*, with the roots of many species of vascular plants. The plant benefits mostly through an enhancement of **nutrient** uptake, while the fungus benefits through access to metabolites. Certain fungi are also partners in the symbioses with algae known as **lichens**. *See also* Fungicide

Fungicide

A fungus is a tiny plant-like organism that obtains its nourishment from dead or living organic matter. Some examples of **fungi** include mushrooms, toadstools, smuts, molds, rusts, and mildew.

Fungi have long been recognized as a serious threat to natural plants and human crops. They attack food both while it is growing and also after it has been harvested and placed into storage. One of the great agricultural disasters of the second half of the twentieth century was caused by a fungus. In 1970, the fungus that causes southern corn-leaf blight swept through the southern and midwestern United States and destroyed about 15% of the nation's corn crop. Potato blight, wheat rust, wheat smut, and grape mildew are other important disasters caused by fungi.

Chestnut blight is another example of the devastation that can be caused by fungi. Until 1900, chestnut trees were common in many parts of the United States. In 1904, however, chestnut trees from Asia were imported and planted in parts of New York. The imported trees carried with them a fungus that attacked and killed the native chestnut trees. Over a period of five decades, the native trees were all but totally eliminated from the eastern part of the country.

It is hardly surprising that humans began looking for fungicides—substances that will kill or control the growth of fungi—early on in history. The first of these fungicides was a naturally occurring substance, sulfur. One of the most effective of all fungicides, Bordeaux mixture was invented in 1885. Bordeaux mixture is a combination of two inorganic compounds, **copper** sulfate and lime.

With the growth of the chemical industry during the twentieth century, a number of synthetic fungicides have been invented; these include ferbam, ziram, captan, naban, dithiocarbonate, quinone, and 8-hydroxyquinoline.

For a period of time, compounds of **mercury** and **cadmium** were very popular as fungicides. Until quite recently, for example, the compound methylmercury was widely used by farmers in the United States who used it to protect growing plants and to treat stored grains.

During the 1970s, however, evidence began to accumulate about a number of adverse effects of mercury- and cadmium-based fungicides. The most serious effects were observed among birds and small animals who were exposed to sprays and dusting or who ate treated grain. A few dramatic incidents of methylmercury **poisoning** among humans, however, were also recorded. The best known of these was the 1953 disaster at Minamata Bay, Japan.

At first, scientists were mystified by an epidemic that spread through the Minamata Bay area between 1953 and 1961. Some unknown factor caused serious nervous disorders among residents of the region. Some sufferers lost the ability to walk, others developed mental disorders, and still others were permanently disabled. Eventually researchers traced the cause of these problems to methylmercury in fish eaten by residents of the area. For the first time, the terrible effects of the compound had been confirmed.

As a result of the problems with mercury and cadmium compounds, scientists have tried to develop less toxic substitutes for the more dangerous fungicides. Dinocap, binapacryl, and benomyl are three examples of such compounds.

Another approach has been to use **integrated pest management** and to develop plants that are resistant to fungi. The latter approach was used with great success during the corn blight disaster of 1970. Researchers worked quickly to develop strains of corn that were resistant to the corn-leaf blight fungus and by 1971 had provided farmers with seeds of the new strain. *See also* Minamata disease

Furans

Furans are by-products of natural and industrial processes and are considered environmental pollutants. They are chemical substances found in small amounts in the **environment**, including air, water and **soil**. They are also present in some foods. Although the amounts are small, they are persistent and remain in the environment for long periods of time, also accumulating in the food chain. The U.S. Environmental Protection Agency's (EPA) Persistent Bioaccumulative and Toxic (PBT) Chemical Program classifies furans as priority PBTs.

Furans belong to a class of organic compounds known as heterocyclic aromatic **hydrocarbons**. The basic furan structure is a five-membered ring consisting of four atoms of **carbon** and one oxygen. Various types of furans have additional atoms and rings attached to the basic furan structure. Some furans are used as solvents or as raw materials for synthesizing **chemicals**.

Polychlorinated dibenzofurans (PCDFs) are of particular concern as environmental pollutants. These are three-ringed structures, with two rings of six carbon atoms each (**benzene** rings) attached to the furan. Between one and eight **chlorine** atoms are attached to the rings. There are 135 types of PCDFs, whose properties are determined by the number and position of the chlorine atoms. PCDFs are closely related to polychlorinated dioxins (PCDDs) and **polychlorinated biphenyls** (PCBs). These three types of toxic compounds often occur together and PCDFs are major contaminants of manufactured PCBs. In fact, the term **dioxin** commonly refers to a subset of these compounds that have similar chemical structures and toxic mechanisms. This subset includes 10 of the PCDFs, as well as seven of the PCDDs and 12 of the PCBs. Less frequently, the term dioxin is used to refer to all 210 structurally-related PCDFs and PCDDs, regardless of their toxicities.

Furans are present as impurities in various industrial chemicals. PCDFs are trace byproducts of most types of **combustion**, including the **incineration** of chemical, industrial, medical, and municipal waste, the burning of wood, **coal**, and peat, and **automobile emissions**. Thus most PCDFs are released into the environment through smokestacks. However the backyard burning of common household trash in barrels has been identified as potentially one of the largest sources of dioxin and furan emissions in the United States. Because of the lower temperatures and inefficient combustion in burn barrels, they release more PCDFs than municipal incinerators. Some industrial chemical processes, including chlorine bleaching in **pulp and paper mills**, also produce PCDFs.

PCDFs that are released into the air can be carried by currents to all parts of the globe. Eventually they fall to earth and are deposited in soil, sediments, and surface water. Although furans are slow to volatilize and have a low solubility in water, they can wash from soils into bodies of water, evaporate, and be re-deposited elsewhere. Furans have been detected in soils, surface waters, sediments, plants, and animals throughout the world, even in arctic organisms. They are very resistant to both chemical breakdown and biological degradation by **microorganisms**.

Most people have low but detectable levels of PCDDs and PCDFs in their tissues. Furans enter the food chain from soil, water, and plants. They accumulate at the higher levels of the food chain, particularly in fish and animal fat. The concentrations of PCDDs and PCDFs may be hundreds or thousands of times higher in aquatic organisms than in the surrounding waters. Most humans are exposed to furans through animal fat, milk, eggs, and fish. Some of the highest levels of furans are found in human breast milk. The presence of dioxins and furans in breast milk can lead to the development of soft, discolored molars in young children. Industrial workers can be exposed to furans while handling chemicals or during industrial accidents.

Furans bind to aromatic hydrocarbon receptors in cells throughout the body, causing a wide range of deleterious effects, including developmental defects in fetuses, infants, and children. Furans also may adversely affect the reproductive and immune systems. At high exposure levels, furans can cause chloracne, a serious acne-like skin condition. Furan itself, as well as PCDFs, are potential cancer-causing agents.

The switch from leaded to unleaded **gasoline**, the halting of PCB production in 1977, changes in paper manufacturing processes, and new air and **water pollution** controls, have reduced the emissions of furans. In 1999 the United States, Canada, and Mexico agreed to cooperate to further reduce the release of dioxins and furans.

On May 23, 2001, EPA Administrator Christie Whitman, along with representatives from more than 90 other countries, signed the global treaty on **Persistent Organic Pollutants**. The treaty phases out the manufacture and use of 12 toxic chemicals, the so-called "dirty dozen," that includes furans. The United States opposed a complete ban on furans and dioxins; thus, unlike eight of the other chemicals that were banned outright, the treaty calls for the use of dioxins and furans to be minimized and eliminated where feasible.

Future generations

According to demographers, a generation is an age-cohort of people born, living, and dying within a few years of each other. Human generations are roughly defined categories, and the demarcations are not as distinct as they are in many other **species**. As the Scottish philosopher David Hume noted in the eighteenth century, generations of human beings are not like generations of butterflies, who come into existence, lay their eggs, and die at about the same time, with the next generation hatching thereafter. But distinctions can still be made, and future generations are all age-cohorts of human beings who have not yet been born.

The concept of future generations is central to **environmental ethics** and **environmental policy**, because the health and well-being—indeed the very existence—of human beings depends on how people living today care for the natural **environment**.

Proper stewardship of the environment affects not only the health and well-being of people in the future but their character and identity. In *The Economy of the Earth*, Mark Sagoff compares environmental damage to the loss of our rich cultural heritage. The loss of all our art and literature would deprive future generations of the benefits we have enjoyed and render them nearly illiterate. By the same token, if we destroyed all our wildernesses and dammed all our rivers, allowing **environmental degradation** to proceed at the same pace, we would do more than deprive people of the pleasures we have known. We would make them into what Sagoff calls "environmental illiterates," or "yahoos" who would neither know nor wish to experience the beauties and pleasures of the natural world. "A pack of yahoos," says Sagoff, "will like a junkyard environment" because they will have known nothing better.

The concept of future generations emphasizes both our ethical and aesthetic obligations to our environment. In relations between existing and future generations, however, the present generation holds all the power. While we can affect them, they can do nothing to affect us. Though, as some environmental philosophies have argued, our moral code is in large degree based on reciprocity, the relationship between generations cannot be reciprocal. Adages such as "like for like," and "an eye for an eye," can apply only among contemporaries. Since an adequate environmental ethic would require that moral consideration be extended to include future people, views of justice based on the norm of reciprocity may be inadequate.

A good deal of discussion has gone into what an alternative environmental ethic might look like and on what it might be based. But perhaps the important point to note is that the treatment of generations yet unborn has now become a lively topic of philosophical discussion and political debate. *See also* Environmental education; Environmentalism; Intergenerational justice

Gaia hypothesis

The Gaia hypothesis was developed by British biochemist James Lovelock, and it incorporates two older ideas. First, the idea implicit in the ancient Greek term *Gaia*, that the earth is the mother of all life, the source of sustenance for all living beings, including humans. Second, the idea that life on earth and many of earth's physical characteristics have coevolved, changing each other reciprocally as the generations and centuries pass.

Lovelock's theory contradicts conventional wisdom, which holds "that life adapted to the planetary conditions as it and they evolved their separate ways." The Gaia hypothesis is a startling break with tradition for many, although ecologists have been teaching the **coevolution** of organisms and **habitat** for at least several decades, albeit more often on a local than a global scale.

The hypothesis also states that Gaia will persevere no matter what humans do. This is undoubtedly true, but the question remains: in what form, and with how much diversity? If humans don't change the nature and scale of some of their activities, the earth could change in ways that people may find undesirable—loss of **biodiversity**, more "weed" **species**, increased **desertification**, etc.

Many people, including Lovelock, take the Gaia hypothesis a step further and call the earth itself a living being, a long-discredited organismic analogy. Recently a respected **environmental science** textbook defined the Gaia hypothesis as a "proposal that Earth is alive and can be considered a system that operates and changes by feedbacks of information between its living and nonliving components." Similar sentences can be found quite commonly, even in the scholarly literature, but upon closer examination they are not persuasive. A furnace operates via a positive and negative feedback system—does that imply it is alive? Of course not. The important message in Lovelock's hypothesis is that the health of the earth and the health of its inhabitants are inextricably intertwined. *See also* Balance of nature; Biological community; Biotic community; Ecology; Ecosystem; Environment; Environmentalism; Evolution; Nature; Sustainable biosphere

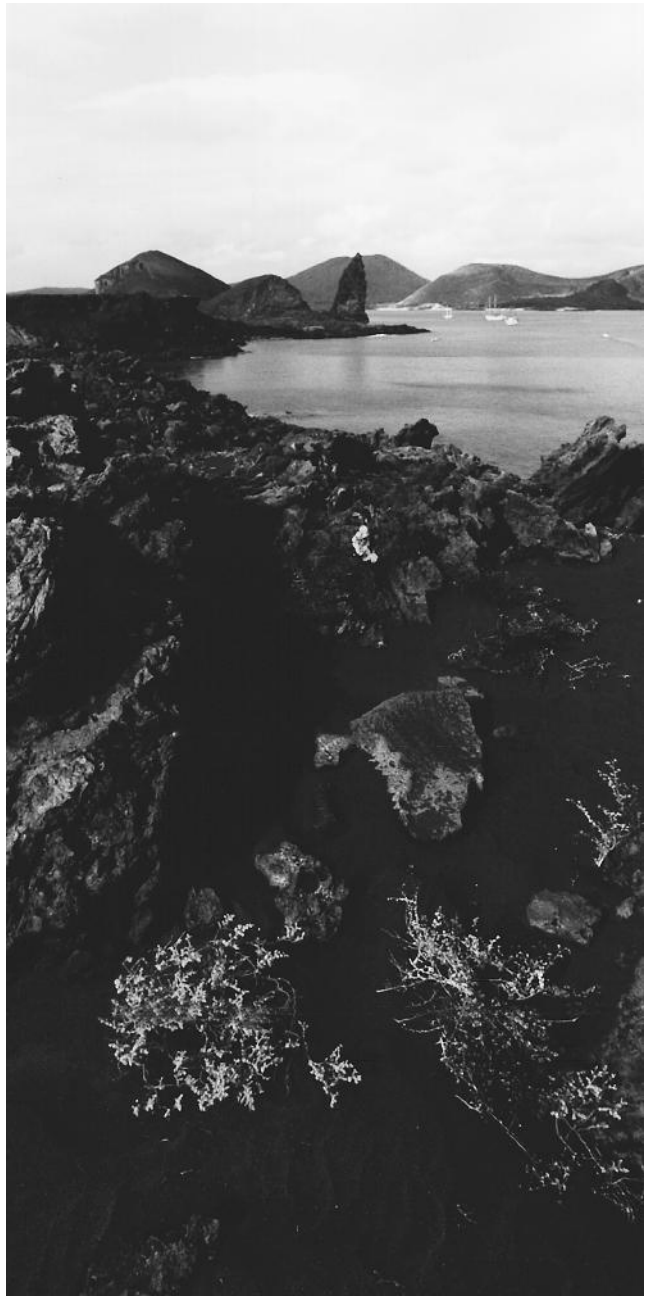
Galápagos Islands



Within the theory of **evolution**, the concept of adaptive radiation (evolutionary development of several **species** from a single parental stock) has had as its prime example, a group of birds known as Darwin's finches. Charles Darwin discovered and collected specimens of these birds from the Galápagos Islands in 1835 on his five-year voyage around the world aboard the HMS *Beagle*. His cumulative experiences, copious notes, and vast collections ultimately led to the publication of his monumental work, *On the Origin of Species*, in 1859. The Galápagos Islands and their unique assemblage of plants and animals were an instrumental part of the development of Darwin's evolutionary theory.

The Galápagos Islands are located at 90° W longitude and 0° latitude (the equator), about 600 mi (965 km) west Ecuador. These islands are volcanic in origin and are about 10 million years old. The original colonization of the Galápagos Islands occurred by chance transport over the ocean as indicated by the gaps in the **flora** and **fauna** of this archipel-

ago compared to the mainland. Of the hundreds of species of birds along the northwestern South American coast, only seven species colonized the Galápagos Islands. These evolved into 57 resident species, 26 of which are endemic to the islands, through adaptive radiation. The only native land mammals are a rat and a bat. The land reptiles include iguanas, a single species each of snake, lizard, and gecko, and the Galápagos giant tortoise (*Geochelone elephantopus*). No amphibians and few insects or mollusks are found in the Galápagos. The flora has large gaps as well—no conifers or palms have colonized these islands. Many of the open niches have been filled by the colonizing groups. The tortoises and iguanas are large and have filled niches normally occupied by mammalian herbivores. Several plants, such as the prickly pear cactus, have attained large size and occupy the ecological position of tall trees.

The most widely known and often used example of adaptive radiation is Darwin's finches, a group of 14 species of birds that arose from a single ancestor in the Galápagos Islands. These birds have specialized on different islands or into niches normally filled by other groups of birds. Some are strictly seed eaters, while others have evolved more warbler-like bills and eat insects, still others eat flowers, fruit, and/or nectar, and others find insects for their diet by digging under the bark of trees, having filled the **niche** of the woodpecker. Darwin's finches are named in honor of their discoverer, but they are not referred to as Galápagos finches because there is one of their numbers that has colonized Cocos Island, located 425 mi (684 km) north-northeast of the Galápagos.

Because of the Galápagos Islands' unique **ecology**, scenic beauty and tropical **climate**, they have become a mecca for tourists and some settlement. These human activities have introduced a host ofenvironmental problems, including **introduced species** of goats, pigs, rats, dogs, and cats, many of which become feral and damage or destroy nesting bird colonies by preying on the adults, young, or eggs. Several races of giant tortoise have been extirpated or are severely threatened with **extinction**, primarily due to exploitation for food by humans, destruction of their food resources by goats, or predation of their hatchlings by feral animals. Most of the 13 recognized races of tortoise have populations numbering only in the hundreds. Three races are tenuously maintaining populations in the thousands, one race has not been seen since 1906, but it is thought to have disappeared due to natural causes, another race has a population of about 25 individuals, and the Abingdon Island tortoise is represented today by only one individual, "Lonesome George," a captive male at the Charles Darwin Biological Station. For most of these tortoises to survive, an active capture or extermination program of the feral animals will have to continue. One other potential threat to the Galápagos Islands is tourism. Thousands of tourists visit these islands each year and their numbers can exceed the limit deemed sustainable by the Ecuadoran government. These tourists have had, and will continue to have, an impact on the

Coastline in the Galápagos Islands. (Photograph by Anthony Wolff. Phototake NYC. Reproduced by permission.)

Birute Marija Filomena Galdikas (1948 –)

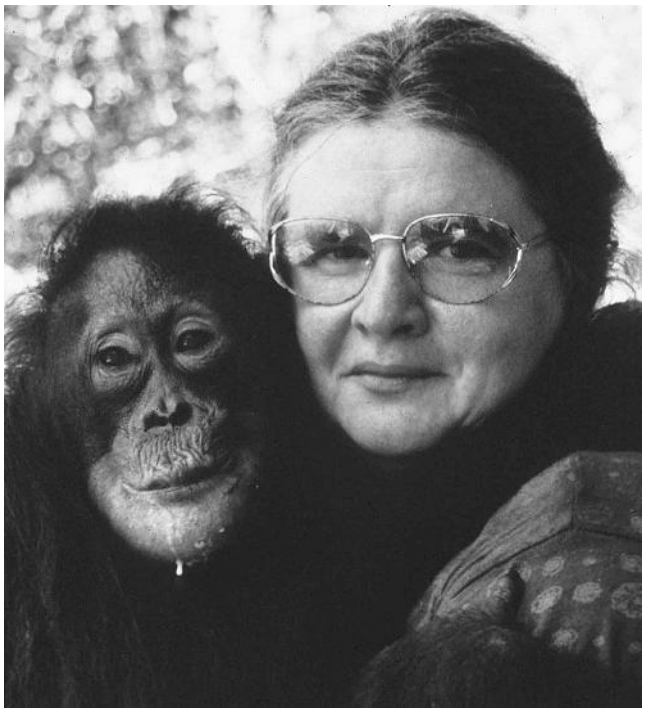
Lithuanian/Canadian primatologist

The world's leading expert on orangutans, Birute Galdikas has dedicated much of her life to studying the orangutans of Indonesia's Borneo and Sumatra islands. Her work, which has complemented that of such other scientists as **Dian Fossey** and **Jane Goodall**, has led to a much greater understanding of the primate world and more effective efforts to protect orangutans from the effects of human infringement. Galdikas has also been credited with providing valuable insights into human culture through her decades of work with primates. She discusses this aspect of her work in her 1995 autobiography, Reflections of Eden: My Years with the Orangutans of Borneo.

Galdikas was born on May 10, 1948 in Wiesbaden in what was then West Germany, while her family was en route from their native Lithuania. She was the first of four children. The family moved to Toronto, Canada when she was two, and she grew up in that city. As a child, Galdikas was already enamored of the natural world, and spent much of her time in local parks and reading books on jungles and their inhabitants. She was already especially interested in orangutans. The Galdikas family eventually moved to Los Angeles, where Birute attended the local campus of the University of California. She earned a BA there in 1966 and immediately began work on a master's degree in anthropology. Galdikas had already decided to start a long-term study of orangutans in the rain forests of Indonesia, where most of the world's last remaining wild individuals live.

Galdikas began to realize her dream in 1969 when she approached famed paleoanthropologist Louis Leakey after he gave a lecture at UCLA. Leakey had helped launch the research efforts of Fossey and Goodall, and she asked him to do the same for her. He agreed, and by 1971 had helped her raise enough money to get started. With her first husband, Galdikas traveled to southern Borneo's Tanjung Puting **National Park** in East Kalimantan to start setting up her research station. Such challenges as huge leeches, extremely toxic plants, perpetual dampness, swarms of insects, and aggressive viruses slowed Galdikas down, but did not ruin her enthusiasm for her new project.

After finally locating the area's elusive **orangutan** population, Galdikas faced the difficulty of getting the shy animals accustomed enough to her presence that they would permit her to watch them even from a distance.



Once Galdikas accomplished this, she was able to begin documenting some of the traits and habits of the little-studied orangutans. She compiled a detailed list of staples in the animals' diets, discovered that they occasionally eat meat, and recorded their complex behavioral interactions.

Eventually, the animals came to accept Galdikas and her husband so thoroughly that their camp was often overrun by them. Galdikas recalled in a 1980 National Geographic article that she sometimes felt as though she were "surrounded by wild, unruly children in orange suits who had not yet learned their manners." Meanwhile, she applied her findings to her UCLA education, earning both her master's degree and doctorate in 1978.

During her first decade on Borneo, Galdikas founded the Orangutan Project, which has since been funded by such organizations as the National Geographic Society, the **World Wildlife Fund**, and **Earthwatch**. The Project not only carries out primate research, but also rehabilitates hundreds of former captive orangutans. She also founded the Los Angeles-based nonprofit Orangutan Foundation International in 1987.

From 1996 to 1998, Galdikas served as a senior adviser to the Indonesian Forestry Ministry on orangutan issues as that government attempted to rectify the mistreatment of the animals and the mismanagement of their dwindling **rain forest habitat**. As part of these efforts, the Jakarta government also helped Galdikas establish the Orangutan Care Center and Quarantine near Pangkalan Bun, which opened in 1999. This center has since cared for many of the primates injured or displaced by the devastating fires in the Borneo rain forest in 1997–1998.

Divorced in 1979, Galdikas married a native Indonesian man of the Dayak tribe in 1981. She has one son with her first husband and two children with her second. Galdikas and her second husband currently live in a Dayak village, but Galdikas travels to Canada once a year to visit her first son. She became a visiting professor at Simon Fraser University in 1981, but since then has been appointed full professor. Besides her work, Galdikas reportedly most enjoys playing with her children, reading, walking, and listening to native Indonesian music. She has been featured on such popular television shows as "Good Morning, America" and "Eye to Eye," using such exposure to increase public aware-

Game animal

Birds and mammals commonly hunted for sport. The major groups include upland game birds (quail, pheasant, and partridge), waterfowl (ducks and geese), and big game (deer, antelope, and bears). Game animals are protected to varying degrees throughout most of the world, and **hunting** levels are regulated through the licensing of hunters as well as by seasons and bag limits. In the United States, state **wildlife** agencies assume primary responsibility for enforcing hunting regulations, particularly for resident or non-migratory **species**. The **Fish and Wildlife Service** shares responsibility with state agencies for regulating harvests of migratory game animals, principally waterfowl.

Game preserves

Game preserves (also known as game reserves, or **wildlife** refuges) are a type of protected area in which **hunting** of certain **species** of animals is not allowed, although other kinds of resource harvesting may be permitted. Game preserves are usually established to conserve populations of larger game species of mammals or waterfowl. The protection from hunting allows the hunted species to maintain relatively large populations within the sanctuary. However, animals may be legally hunted when they move outside of the reserve during their seasonal migrations or when searching for additional **habitat**.

Game preserves help to ensure that populations of hunted species do not become depleted through excessive harvesting throughout their range. This **conservation** allows the species to be exploited in a sustainable fashion over the larger landscape.

Although hunting is not allowed, other types of resource extraction may be permitted in game reserves, such as timber harvesting, livestock grazing, some types of cultivated agriculture, mining, and exploration and extraction of **fossil fuels**. However, these land-uses are managed to ensure that the habitat of game species is not excessively damaged. Some game preserves are managed as true ecological reserves, where no extraction of **natural resources** is allowed. However, low-intensity types of land-use may be permitted in these more comprehensively protected areas, particularly non-consumptive **recreation** such as hiking and wildlife viewing.

Game preserves as a tool in conservation

The term "conservation" refers to the wise (i.e., sustainable) use of natural resources. Conservation is particularly relevant to the use of renewable resources, which are capable of regenerating after a portion has been harvested. Hunted species of animals are one type of renewable resource, as are timber, flowing water, and the ability of land to support the growth of agricultural crops. These renewable resources have the potential to be harvested forever, as long as the rate of exploitation is equal to or less than the rate of regeneration. However, potentially renewable resources can also be harvested at a rate exceeding their regeneration. This is known as over-exploitation, a practice that causes the stock of the resource to decline and may even result in its irretrievable collapse.

Wildlife managers can use game preserves to help conserve populations of hunted species. Other methods of conservation of game animals include: (1) regulation of the

time of year when hunting can occur; (2) setting of "bag limits" that restrict the maximum number of animals that any hunter can harvest; (3) limiting the total number of animals that can be harvested in a particular area, and; (4) restricting the hunt to certain elements of the population. Wildlife managers can also manipulate the habitat of game species so that larger, more productive populations can be sustained, for example by increasing the availability of food, water, shelter, or other necessary elements of habitat. In addition, wildlife managers may cull the populations of natural predators to increase the numbers of game animals available to be hunted by people.

Some or all of these practices, including the establishment of game preserves, may be used as components of an integrated game management system. Such systems may be designed and implemented by government agencies that are responsible for managing game populations over relatively large areas such as counties, states, provinces, or entire countries.

Conservation is intended to benefit humans in their interactions with other species and ecosystems, which are utilized as valuable natural resources. When defined in this way, conservation is very different from the preservation of indigenous species and ecosystems for their ecocentric and biocentric values, which are considered important regardless of any usefulness to humans or their economic activities.

Examples of game preserves

The first **national wildlife refuge** in the United States was established by President **Theodore Roosevelt** in 1903. This was a breeding site for brown pelicans (*Pelecanus occidentalis*) and other birds in Florida. The U.S. national system of wildlife refuges now totals some 437 sites covering 91.4 million acres (37 million ha); an additional 79 million acres (32 million ha) of habitat are protected in national parks and monuments. The largest single wildlife reserve is the Alaska Maritime Wildlife Refuge, which covers 3.5 million acres (1.4 million ha); in fact, about 85% of the national area of **wildlife refuges** is in Alaska. Most of the national wildlife refuges protect migratory, breeding, and wintering habitats for waterfowl, but others are important for large mammals and other species. Some wildlife refuges have been established to protect **critical habitat** of **endangered species**, such as the Aransas Wildlife Refuge in coastal Texas, which is the primary wintering grounds of the **whooping crane** (*Grus americana*). Since 1934, sales of *Migratory Bird Hunting Stamps*, or "duck stamps," have been critical to providing funds for the acquisition and management of federal wildlife refuges in the United States.

Although hunting is not permitted in many National wildlife refuges, in 1988, closely regulated hunting was permitted in 60% of the refuges, and fishing was allowed in 50%. In addition, some other resource-related activities are allowed in some refuges. Depending on the site, it may be possible to harvest timber, graze livestock, engage in other kinds of agriculture, or explore for or mine metals or fossil fuels. The various components of the multiple-use plans of particular national wildlife refuges are determined by the Secretary of the Interior. Any of these economically important activities may cause damage to wildlife habitats, and this has resulted in intense controversy between economic interests and some environmental groups. Environmental organizations such as the **Sierra Club**, **Ducks Unlimited**, and the Audubon Society have lobbied federal legislators to further restrict exploration and extraction in national wildlife refuges, but business interests demand greater access to valuable resources within national wildlife refuges.

Many states and provinces also establish game preserves as a component of wildlife-management programs on their lands. For example, many jurisdictions in eastern North America have set up game preserves for management of populations of white-tailed deer (*Odocoileus virginianus*), a widely hunted species. Game preserves are also used to conserve populations of mule deer (*Odocoileus hemionus*) and elk (*Cervus canadensis*) in more western regions of North America.

Some other types of protected areas, such as state, provincial, and national parks are also effective as wildlife preserves. These protected areas are not primarily established for the conservation of natural resources—rather, they are intended to preserve natural ecosystems and wild places for their **intrinsic value**. Nevertheless, relatively large and productive populations of hunted species often build up within parks and other large ecological reserves, and the surplus animals are commonly hunted in the surrounding areas. In addition, many protected areas are established by non-governmental organizations, such as **The Nature Conservancy**, which has preserved more than 16 million acres (6.5 million ha) of natural habitat throughout the United States.

Yellowstone National Park is one of the most famous protected areas in North America. Hunting is not allowed in Yellowstone, and this has allowed the build-up of relatively large populations of various species of big-game mammals, such as white-tailed deer, elk, **bison** (*Bison bison*), and **grizzly bear** (*Ursus arctos*). Because of the large populations in the park, the overall abundance of game species on the greater landscape is also larger. This means that a relatively high intensity of hunting can be supported. This is considered important because it provides local people with meat and subsistence as well as economic opportunities through guiding and the marketing of equipment, accommodations, food, fuel, and other necessities to non-local hunters.

By providing a game-preserve function for the larger landscape, wildlife refuges and other kinds of protected areas

help to ensure that hunting can be managed to allow populations of exploited species to be sustained, while providing opportunities for people to engage in subsistence and economic activities.

Gamma ray

High energy forms of electromagnetic radiation with very short wavelengths. Gamma rays are emitted by cosmic sources or by **radioactive decay** of atomic nuclei which occurs during nuclear reactions or the detonation of **nuclear weapons**. Gamma rays are the most penetrating of all forms of nuclear radiation. They travel about 100 times deeper into human tissue than beta particles and 10,000 times deeper than alpha particles. Gamma rays cause chemical changes in cells through which they pass. These changes can result in the cells' death or the loss of their ability to function properly. Organisms exposed to gamma rays may suffer illness, genetic damage, or death. Cosmic gamma rays do not usually pose a danger to life because they are absorbed as they travel through the **atmosphere**. *See also* Ionizing radiation; Radiation exposure; Radioactive fallout

Mohandas Karamchand Gandhi (1869 – 1948)

Indian Religious leader

Mohandas Karamchand Gandhi led the movement that freed India from colonial occupation by the British. His leadership was based not only on his political vision but also on his moral, economic, and personal philosophies. Gandhi's beliefs have influenced many political movements throughout the world, including the civil rights movement in the United States, but their relevance to the modern environmental movement has not been widely recognized or understood until recently.

In developing the principles that would enable the Indian people to form a united independence movement, one of Gandhi's chief concerns was preparing the groundwork for an economy that would allow India to be both self-sustaining and egalitarian. He did not believe that an independent economy in India could be based on the Western model; he considered a consumer economy of unlimited growth impossible in his country because of the huge population base and the high level of poverty. He argued instead for the development of an economy based on the careful use of indigenous **natural resources**. His was a philosophy of **conservation**, and he advocated a lifestyle based on limited consumption, **sustainable agriculture**, and the utilization of labor resources instead of imported technological development.

Gandhi's plans for India's future were firmly rooted both in moral principles and in a practical recognition of its economic strengths and weaknesses. He believed that the key to an independent national economy and a national sense of identity was not only indigenous resources but indigenous products and industries. Gandhi made a point of wearing only homespun, undyed cotton clothing that had been handwoven on cottage looms. He anticipated that the practice of wearing homespun cotton cloth would create an industry for a product that had a ready market, for cotton was a resource that was both indigenous and renewable. He recognized that India's major economic strength was its vast labor pool, and the low level of technology needed for this product would encourage the development of an industry that was highly decentralized. It could provide employment without encouraging mass **migration** from rural to urban areas, thus stabilizing rural economies and national demography. The use of cotton textiles would also prevent dependence on expensive synthetic fabrics that had to be imported from Western nations, consuming scarce foreign exchange. He also believed that synthetic textiles were not suited to India's **climate**, and that they created an undesirable distinction between the upper classes that could afford them and the vast majority that could not.

The essence of his economic planning was a philosophical commitment to living a simple lifestyle based on need. He believed it was immoral to kill animals for food and advocated **vegetarianism**; advocated walking and other simple forms of **transportation** contending that India could not afford a car for every individual; and advocated the integration of ethical, political, and economic principles into individual lifestyles. Although many of his political tactics, particularly his strategy of civil disobedience, have been widely embraced in many countries, his economic philosophies have had a diminishing influence in a modern, independent India, which has been pursuing sophisticated technologies and a place in the global economy. But to some,

Mohandas Karamchand Gandhi. (AP/Wide World Photos. Reproduced by permission.)

his work seems increasingly relevant to a world with limited resources and a rapidly growing population.

Garbage

In 1999, the United States generated 230 million tons of **municipal solid waste**, compared with 195 million tons in 1990, according to **Environmental Protection Agency** (EPA) estimates. On average, each person generated 4.6 lb (2.1 kg) of such waste per day in 1999, and the EPA expects that amount to continue increase. That waste includes cans, bottles, newspapers, paper and plastic packages, uneaten food, broken furniture and appliances, old tires, lawn clippings, and other refuse. This waste can be placed in landfills, incinerated, recycled, or in some cases composted.

Landfilling—waste disposed of on land in a series of layers that are compacted and covered, usually with soil—is the main method of **waste management** in this country, accounting for about 57%of the waste. But old landfills are being closed and new ones are hard to site because of community opposition. Landfills once were open dumps, causing unsanitary conditions, **methane** explosions, and releases of hazardous **chemicals** into **groundwater** and air. Old dumps make up 22% of the sites on the Superfund **National Priorities List**. Today, landfills must have liners, gas collection systems, and other controls mandated under Subtitle D of the **Resource Conservation and Recovery Act** (RCRA).

Incineration has been popular among **solid waste** managers because it helps to destroy bacteria and toxic chemicals and to reduce the volume of waste. But public opposition, based on fears that toxic metals and other chemical emissions will be released from incinerators, has made the siting of new facilities extremely difficult. In the past, garbage burning was done in open fields, in dumps, or in backyard drums, but the **Clean Air Act** (1970) banned open burning, leading to new types of incinerators, most of which are designed to generate energy.

Recycling, which consists of collecting materials from waste streams, preparing them for market, and using those materials to manufacture new products, is catching national attention as a desirable waste management method. As of 1999, all states and the District of Columbia had some type of statewide recycling law aimed at promoting greater recycling of glass, paper, metals, **plastics**, and other materials. Used oil, household batteries, and lead-acid automotive batteries are recyclable waste items of particular concern because of their toxic constituents.

Composting is a waste management approach that relies on heat and microorganisms—mostly bacteria and fungi—to decompose yard wastes and food scraps, turning them into a nutrient-rich mix called **humus** or compost. This mix can be used as **fertilizer**. However, as with landfills and incinerators, composting facilities have been difficult to site because of community opposition, in part because of the disagreeable smell generated by some composting practices.

Recently, waste managers have shown interest in source reduction, reducing either the amount of garbage generated in the first place or the toxic ingredients of garbage. Reusable blankets instead of throw-away cardboard packaging for protecting furniture is one example of source reduction. Businesses are regarded as a prime target for source reduction, such as implementing double-sided photocopying

to save paper, because the approach offers potentially large cost savings to companies.

Garbage Project

The **Garbage** Project was founded in 1973, shortly after the first **Earth Day**, by William Rathje, professor of anthropology, and fellow archaeologists at the University of Arizona. The objective was to apply the techniques and tools of their science to the study of modern civilization by analyzing its garbage.

Using sample analysis and assessing biodegradation, they also hoped to increase their understanding of resource depletion and environmental and landfill-related problems. Because it requires sunlight, moisture, and oxygen, as well as organic material and bacteria, little biodegradation actually takes place in landfills, resulting in perfectly preserved heads of lettuce, 40-year-old hot dogs, and completely legible 50-year-old newspapers.

In *Rubbish: The Archaeology of Garbage*, published in 1992, Rathje and *Atlantic Monthly* managing editor Cullen Murphy discuss some of the data gleaned from the project. For example, the accumulation of refuse has raised the City of New York 6–30 ft (1.8–9 m) since its founding. Also, the largest proportion—40%—of landfilled garbage is paper, followed by the leftovers from building construction and demolition. In fact, newspapers alone make up about 13% of the total volume of trash.

Just as interesting as what they found was what they did not find. Contrary to much of public opinion, fast-food packaging made up only one-third of 1% of the total volume of trash landfilled between 1980 and 1989, while expanded **polystyrene** foam accounted for no more than 1%. Even **disposable diapers** averaged out at only 1% by weight of the total **solid waste** contents (1.4% by volume). Of all the garbage examined, **plastics** constituted from 20–24%. Surveys of several national landfills revealed that organic materials made up 40–52% of the total volume of waste.

The Garbage Project also debunked the idea that the United States is running out of space for landfills. While it is true that many landfills have been shut down, it is also true that many of those were quite small to begin with and that they now pose fewer environmental hazards. It is estimated that one **landfill** 120 ft (35.4 m) deep and measuring 44 mi^2 (71 km^2) would adequately handle the needs of the entire nation for the next 100 years (assuming current levels of waste production).

In "A Perverse Law of Garbage," Rathje extrapolated from "Parkinson's Law" to define his Parkinson's Law of Garbage: "Garbage expands so as to fill the receptacles available for its containment." As evidence he cites a Garbage Project study of the recent mechanization of garbage pick-up in some larger cities and the ensuing effects. As users were provided with increasingly larger receptacles (in order to accommodate the mechanized trucks), they continued to fill them up. Rathje attributes this to the newfound convenience of disposing of that which previously had been consigned to the basement or secondhand store, and concludes that the move to automation may be counterproductive to any attempt to reduce garbage and increase **recycling**.

Garbology

The study of **garbage**, through either archaeological excavation of landfills or analysis of fresh garbage, to determine what the composition of **municipal solid waste** says about the society that generated it. The term is associated with the **Garbage Project** of the University of Arizona (Tucson), co-directed by William Rathje and Wilson Hughes, which began studying trash in 1973 and excavating landfills in 1987. They found that little degradation occurs in landfills; New York newspapers from 1949 and an ear of corn discarded in 1971 were found intact. Unexpectedly, the project also found that **plastics** make up less than one percent of the total volume of landfills.

Gardens

Gasohol

Gasohol is a term used for the mixture of 10% ethyl alcohol (also called **ethanol** or grain alcohol) with **gasoline**. Ethanol raises the **octane rating** of lead-free **automobile** fuel and significantly decreases the **carbon monoxide** released from tailpipes. It has also been promoted as a means of reducing corn surpluses. By 2001, 2.2 billion gal (8.3 billion l) were being produced a year and this number is expected to rise to 4.6 billion gal (17.4 billion l). However, ethanol also raises the vapor pressure of gasoline, and it has been reported to increase the release of "evaporative" volatile **hydrocarbons** from the fuel system and oxides of **nitrogen** from the exhaust. These substances are components of urban **smog**, and thus the role of ethanol in reducing **pollution** is controversial.

Gasoline

Crude oil in its natural state has very few practical uses. However, when it is separated into its component parts by the process of fractionation, or refining, those parts have an almost unlimited number of applications.

In the first 60 years after the process of **petroleum** refining was invented, the most important fraction produced was kerosene, widely used as a home heating product. The petroleum fraction slightly lighter than kerosene — gasoline — was regarded as a waste product and discarded. Not until the 1920s, when the **automobile** became popular in the United States, did manufacturers find any significant use for gasoline. From then on, however, the importance of gasoline has increased with automobile use.

The term gasoline refers to a complex mixture of liquid **hydrocarbons** that condense in a fractionating tower at temperatures between 100° and 400°F (40° and 205°C). The hydrocarbons in this mixture are primarily single- and double-bonded compounds containing five to 12 **carbon** atoms.

Gasoline that comes directly from a refining tower, known as naphtha or "straight-run" gasoline, was an adequate fuel for the earliest motor vehicles. But as improvements in internal **combustion** engines were made, problems began to arise. The most serious problem was "knocking."

If a fuel burns too rapidly in an internal combustion engine, it generates a shock wave that makes a "knocking" or "pinging" sound. The shock wave will, over time, also cause damage to the engine. The hydrocarbons that make up straight-run gasolines proved to burn too rapidly for automotive engines developed after 1920.

Early in the development of automotive fuels, engineers adopted a standard for the amount of knocking caused by a fuel and, hence, for the fuel's efficiency. That standard was known as "octane number." To establish a fuel's octane number, it is compared with a very poor fuel (n-heptane), assigned an octane number of zero, and a very good fuel (isooctane), assigned an octane number of 100. The octane number of straight-run gasoline is anywhere from 50 to 70.

As engineers made more improvements in automotive engines after the 1920s, chemists tried to keep pace by developing better fuels. One approach they used was to subject straight-run gasoline (as well as other crude oil fractions) to various treatments that changed the shape of hydrocarbon molecules in the gasoline mixture. One such method, called cracking, involves the heating of straight-run gasoline or another petroleum fraction to high temperatures. The process results in a better fuel from newly-formed hydrocarbon molecules.

Another method for improving the quality of gasoline is catalytic reforming. In this case, the cracking reaction takes place over a catalyst such as **copper**, platinum, rhodium, or other "noble" metal, or a form of clay known as zeolite. Again, hydrocarbon molecules formed in the fraction are better fuels than straight-run gasoline. Gasoline produced by catalytic cracking or reforming has an octane number of at least eighty.

A very different approach to improving gasoline quality is the use of additives, **chemicals** added to gasoline to improve the fuel's efficiency. Automotive engineers learned more than 50 years ago that adding as little as two grams of **tetraethyl lead**, the best-known additive, to one gallon of gasoline raises its octane number by as much as ten points.

Until the 1970s, most gasolines contained tetraethyl **lead**. Then, concerns began to grow about the release of lead to the **environment** during the combustion of gasoline. Lead concentrations in urban air had reached a level five to 10 times that of rural air. Residents of countries with few automobiles, such as Nepal, had only one-fifth the lead in their bodies as did residents of nations such as the United States, with many automotive vehicles.

The toxic effects of lead on the human body have been known for centuries, and risks posed by leaded gasoline became a major concern. In addition, leaded gasoline became a problem because it damaged a car's **catalytic converter**, which reduced air pollutants in exhaust.

Finally, in 1973, the **Environmental Protection Agency** (EPA) acted on the problem and set a time-scale for the gradual elimination of leaded fuels. According to this schedule, the amount of lead was to be reduced from 2 to 3 grams per gallon (the 1973 average) to 0.5 g/gal by 1979. Ultimately, the additive was to be totally eliminated from all gasoline.

The elimination of leaded fuels has been made possible by the invention of new and safer additives. One of the most popular is methyl-t-butyl ether (MTBE). By 1988 MTBE

had become so popular that it was among the 40 most widely produced chemicals in the United States. In 2001, MTBE was asked to be phased out of production in California by 2003.

Yet another approach to improving fuel efficiency is the mixing of gasoline and ethyl or **methanol**. This product, known as **gasohol**, has the advantage of high **octane rating**, lower cost, and reduced **emission** of pollutants, compared to normal gasoline. *See also* Air pollution; Alternative fuels

Gasoline tax

Gasoline taxes include federal, state, county, and municipal taxes imposed on gasoline motor vehicle fuel. In the United States, most of the federal tax is used to fund maintenance and improvements in such **transportation** infrastructures as interstate highways. As of mid-2002, the federal excise tax for gasoline stood at 18.4 cents per gallon, and state excise taxes ranged from 7.5 cents in Georgia to 29 cents in Rhode Island (making the weighted national average state tax 19.97 cents per gallon). In total, the U.S. national average gasoline tax (combining federal and state) was 38 cents per gallon.

Oregon became the first state to institute a tax on gasoline in 1919. By the time the federal government established its own 1 cent gas tax in 1932, every state had a gas tax. After several small increases in the 1930s and 1940s, the gas tax was raised to 3 cents to finance the Highway Trust Fund in 1956. The Trust Fund was earmarked to pay for federal interstate construction and other road work. In 1982, the federal gasoline tax was increased to 9 cents to fund road maintenance and **mass transit**. The tax was hiked again in 1990 to 14.1 cents, and to 18.4 cents in 1993—where it remained as of July 2002.

Over this time, gasoline prices increased from about 20 cents per gallon in 1938 to a U.S. national average of 139.2 cents in May of 2002. The average national gasoline tax (both federal and a weighted average of state taxes) accounts for 30.2% of the retail price of a gallon of gas.

In some countries, diesel fuels are taxed and priced less than gasoline. Commercial vehicles are major consumers of diesel, and lower taxes avoided undue impacts on trucking and commerce. In the United States, diesel is taxed at a higher rate than gasoline—an average of 44 cents per gallon (including 24.3 cents federal tax and the weight average of state taxes). In contrast, **gasohol**, an alternative fuel consisting of 90% gasoline and 10% **ethanol**, has a lower rate of taxation (with a 13.1 cent federal excise tax).

Although federal gasoline taxes are a manufacturer's excise tax, meaning that the government collects the tax directly from the manufacturer, rate hikes are often passed on to consumers at the pump. In this light, gasoline taxes have been criticized as regressive and thus inequitable—i.e., lower income individuals pay a greater share of their income as tax than higher income individuals. Also, the tax as a share of the pump price has been increasing. However, it should be noted that the general trend of the real price of gasoline (adjusted for inflation and including taxes) has been declining for many decades. In addition, **automobile** efficiency (mileage) has been improving and thus the fuel requirements and cost-per-mile-traveled have declined.

These factors can be viewed as largely or completely offsetting the impact of gasoline taxes. For example, Congress attempted in May 1996 to rollback the 4.3 cents tax increase of 1993. The impact of this repeal for a family of four who drive 12,000 miles a year at 20 miles per gallon is a savings of $26, which in the House debates was compared to the cost of a family dinner at McDonald's. On the other hand, a rollback could have bigger consequences for the future upkeep of the country's highways and interstates; a 2000 Congressional report estimated that a repeal of the federal gasoline tax would mean a $5.2 billion annual loss in revenues for the Highway Trust Fund.

Outside of the United States, both gasoline prices and gas tax rates are typically far higher (e.g., gasoline taxes were 307 cents per gallon in the United Kingdom as of March 2002). In addition to funding governments, high gasoline taxes form part of a strategy to encourage the use of public transportation, reduce **pollution**, conserve energy, and improve national security (since most gasoline is imported).

Gastropods

Gastropods are invertebrate animals that make up the largest class in the phylum Mollusca. Examples of common gastropods include all varieties of snails, abalone, limpets, and land and sea slugs. There are over 35,000 existing **species**, as well an additional 15,000 separate fossil species. Gastropods first appeared in the fossil record during the early Cambrian period, approximately 550 million years ago.

This diverse group of animals is characterized by a soft body, made up of three main parts: the head, foot, and visceral mass. The head contains a mouth and often sensing tentacles. The lower portion of the body makes up the foot, which allows slow creeping along rocks and other solid surfaces. The visceral mass is the main part of the body, containing most of the internal organs. In addition to these body parts, gastropods possess a mantle, or fold which secretes a hard, calcium carbonate shell. The single, asymmetrical shell of a gastropod is most often spiral shaped, however, it can be flattened or cone-like. This shell is an important source of protection. Predators have a difficult time accessing the soft flesh inside, especially if there are sharp points on the outside, as there are on the shells of some of the more ornate gastropods. There are also some gastropods, such as slugs and sea hares, that do not have shells or have greatly reduced shells. Some of the shelless types that live in the ocean (i.e., nudibranchs or sea slugs) are able to use stinging cells from prey that they have consumed as a means of protection.

In addition to a spiraling of their shells, the soft bodies of most gastropods undergo 180 degrees of twisting, or torsion, during early development, when one side of the visceral mass grows faster than the other. This characteristic distinguishes gastropods from other molluscs. Torsion results in a U-shaped digestive tract, with the anal opening slightly behind the head. The torsion of the soft body and the spiraling of the shell are thought to be unrelated evolutionary events.

Gastropods have evolved to live in a wide variety of habitats. The great majority are marine, living in the world's oceans. Numerous species live in fresh water, while others live entirely on land. Of those that live in water, most are found on the bottom, attached to rocks or other surfaces. There are even a few species of gastropods without shells, including sea butterflies, that are capable of swimming. Living in different habitats has resulted in a wide variety of structural adaptations within the class Gastropoda. For example, those gastropods that live in water use gills to obtain the oxygen necessary for **respiration**, while their terrestrial relatives have evolved lungs to breathe.

Gastropods are important links in food webs in the habitats in which they live, employing a wide variety of feeding strategies. For example, most gastropods move a rasping row of teeth on a tongue like organ called a radula back and forth to scrape microscopic algae off rocks or the surface of plants. Because the teeth on the radula gradually wear away, new teeth are continuously secreted. Other gastropods have evolved a specialized radula for drilling through shells of animals to get at their soft flesh. For example, the oyster drill, a small east coast gastropod, bores a small hole in the shell of neighboring molluscs such as oysters and clams so that it can consume the soft flesh. In addition, some terrestrial gastropods such as snails use their radula to cut through pieces of leaves for food.

Gastropods are eaten by numerous animals, including various types of fish, birds, and mammals. They are also eaten by humans throughout the world. Abalone, muscular shelled gastropods that cling to rocks, are consumed on the west coast of the United States and in Asia. Fritters and chowder are made from the large, snail-like queen conch on many Caribbean islands. Escargot (snails in a garlicky butter sauce) are a European delicacy.

Gene bank

The term gene bank refers to any system by which the genetic composition of some population is identified and stored. Many different kinds of gene banks have been established for many different purposes. Perhaps the most numerous gene banks are those that consist of plant seeds, known as germ banks.

The primary purpose for establishing a gene bank is to preserve examples of threatened or **endangered species**. Each year, untold numbers of plant and animal **species** become extinct because of natural processes and more com-

monly, as the result of human activities. Once those species become extinct, their gene pools are lost forever.

Scientists want to retain those gene pools for a number of reasons. For example, agriculture has been undergoing a dramatic revolution in many parts of the world over the past half century. Scientists have been making available to farmers plants that grow larger, yield more fruit, are more disease-resistant, and have other desirable characteristics. These plants have been produced by agricultural research in the United States and other nations. Such plants are very attractive to farmers, and they are also important to governments as a way of meeting the food needs of growing populations, especially in **Third World** countries.

When farmers switch to these new plants, however, they often abandon older, more traditional crops that may then become extinct. Although the traditional plants may be less productive, they have other desirable characteristics. They may, for example, be able to survive droughts or other extreme environmental conditions that new plants cannot.

Placing seeds from traditional plants in a gene bank allows them to be preserved. At some later time, scientists may want to study these plants further and perhaps identify the genes that are responsible for various desirable properties of the plants. The **U.S. Department of Agriculture** (USDA) has long maintained a **seed bank** of plants native to the United States. About 200,000 varieties of seeds are stored at the USDA's Station at Fort Collins, Colorado, and another 100,000 varieties are kept at other locations around the country.

Efforts are now underway to establish gene banks for animals, too. Such banks consist of small colonies of the animals themselves. Animal gene banks are desirable as a way of maintaining species whose natural population is very low. Sometimes the purpose of the bank is simply to maintain the species to prevent its becoming extinct. In other cases, species are being preserved because they were once used as farm animals although they have since been replaced by more productive modern hybrid species. The Fayoumi chicken native to Egypt, for example, has now been abandoned by farmers in favor of imported species. The Fayoumi, without some form of protection, is likely to become extinct. Nonetheless, it may well have some characteristics (genes) that are worth preserving.

In recent years, another type of gene bank has become possible. In this kind of gene bank, the actual base sequence of important genes in the human body will be determined, collected, and catalogued. This effort, begun in 1990, is a part of the Human Genome Project effort to map all human genes. *See also* Agricultural revolution; Extinction; Genetic engineering; Population growth

Gene pool

The term gene pool refers to the sum total of all the genetic information stored within any given population. A gene is a specific portion of a DNA (**deoxyribose nucleic acid**) molecule, so a gene pool is the sum total of all of the DNA contained within a population of individuals.

The concept of gene pool is important in ecological studies because it reveals changes that may or may not be taking place within a population. In a population living in an ideal **environment** for its needs, the gene pool is likely to undergo little or no change. If individuals are able to obtain all the food, water, energy, and other resources they need, they experience relatively little stress and there is no pressure to select one or another characteristic.

Changes do occur in gene frequency because of natural factors in the environment. For example, natural **radiation exposure** causes changes in DNA molecules that are revealed as genetic changes. These natural mutations are one of the factors that make possible continuous changes in the genetic constitution of a population that, in turn, allows for **evolution** to occur.

Natural populations seldom live in ideal situations, however, and so they experience various kinds of stress that lead to changes in the gene pool. A classical example of this kind of change was reported by J. B. S. Haldane in 1937. Haldane found that a population of moths gradually became darker in color over time as the trees on which they lived also became darker because of **pollution** from factories. Moths in the population who carried genes for darker color were better able to survive and reproduce than were their lighter-colored cousins, so the composition of the gene pool changed to relieve stress.

Humans have the ability to make conscious changes in gene pools that no other **species** has. Sometimes we make those changes in the gene pools of plants or animals to serve our own needs for food or other resource. Hybridization of plants to produce populations that have some desirable quality such as **resistance** to disease, shorter growing season, or better-tasting fruit. The modern science of **genetic engineering** is perhaps the most specific and deliberate way of changing in gene pools today.

Humans can also change the gene pool of their own species. For example, individuals with various genetic disorders were at one time doomed to death. Our inability to treat diabetes, sickle-cell **anemia**, phenylketonuria, and other hereditary conditions meant that the frequency of the genes causing those disorders in the human gene pool was kept under control by natural forces.

Today, many of those same disorders can be treated by medical or genetic techniques. That results in positive benefit for the individuals who are cured, but raises questions about the quality of the human gene pool overall. Instead of having many of those deleterious genes being lost naturally by an individual's death, they are now retained as part of the gene pool. This fact has at times raised questions about the best way in which medical science should deal with genetic disorders. *See also* Agricultural revolution; Birth defects; Extinction; Gene bank; Population growth

Patt, D. I., and G. R. Patt. *An Introduction to Modern Genetics*. Reading, MA: Addison-Wesley, 1976.

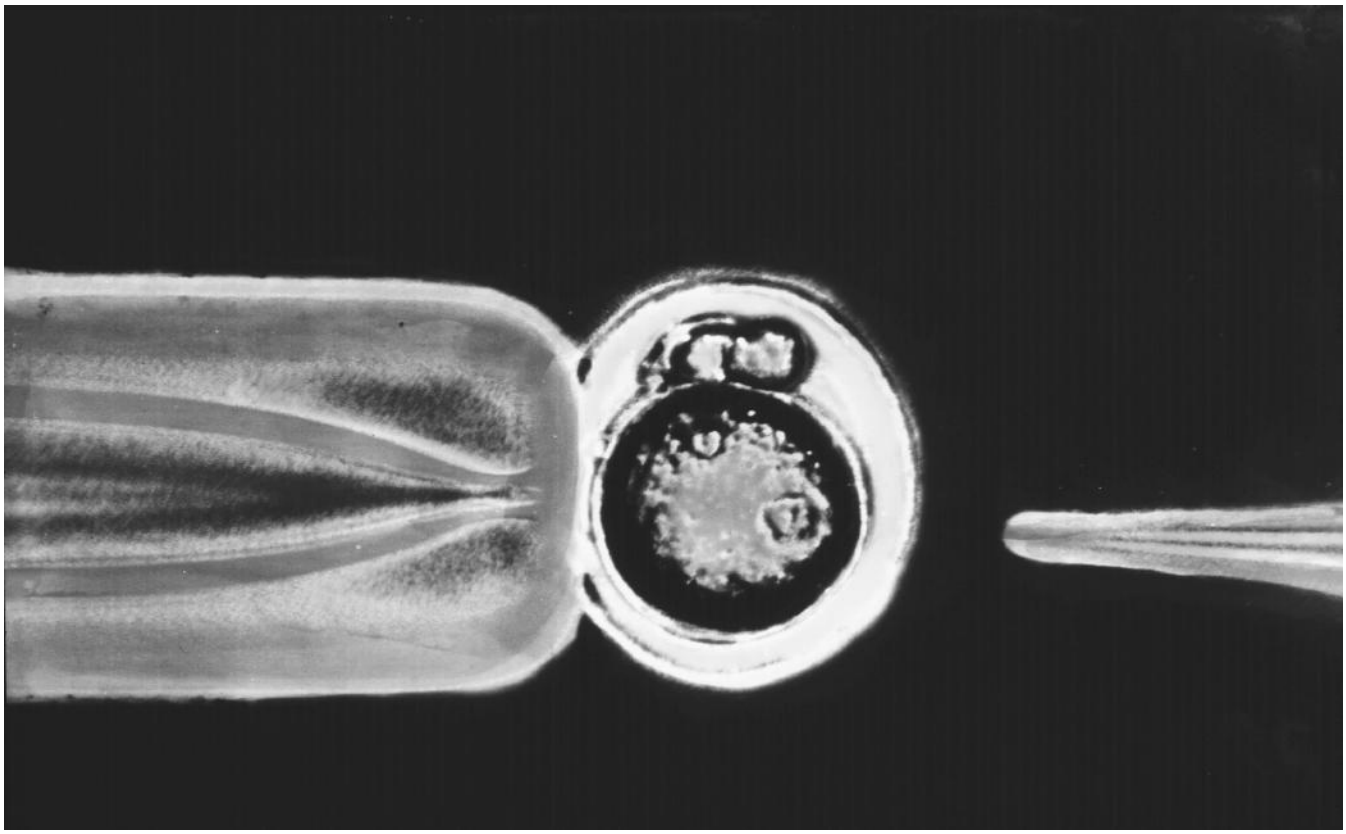
Genetic engineering

Genetic engineering is the manipulation of the hereditary material of organisms at the molecular level. The hereditary material of most cells is found in the chromosomes, and it is made of **deoxyribose nucleic acid** (DNA). The total DNA of an organism is referred to as its genome. In the 1950s, scientists first discovered how the structure of DNA molecules worked and how they stored and transmitted genetic information.

Genetic engineering relies on recombinant DNA technology to manipulate genes. Methods are now available for rapidly sequencing the nucleotides of pieces of DNA, as well as for identifying particular genes of interest, and for isolating individual genes from complex genomes. This allows genetic engineers to alter genetic materials to produce new substances or create new functions.

The biochemical tools used by genetic engineers or molecular biologists include a series of enzymes that can "cut and paste" genes. Enzymes are used to cut a piece of DNA, insert into it a new piece of DNA from another organism, and then seal the joint.

One important group of these are restriction enzymes, of which well over 500 are known. Most restriction enzymes are endonucleases—enzymes that break the double helix of DNA within the molecule, rather than attacking the ends of the helix. Every restriction **enzyme** is given a specific name to identify it uniquely. The first three letters, in italics, indicate the biological source of the enzyme, the first letter being the initial of the genus, the second and third letters being the first two letters of the **species** name. Thus restriction enzymes from ***Escherichia coli*** are called *Eco*, those from *Haemophilus influenzae* are *Hin*, from *Diplococcus pneumoniae* comes *Dpn*, and so on.



The genetic engineer can use a restriction enzyme to locate and cut almost any sequence of bases. Cuts can be made anywhere along the DNA, dividing it into many small fragments or a few longer ones. The results are repeatable: cuts made by the same enzyme on a given sort of DNA will always be the same. Some enzymes recognize sequences as long as six or seven bases; these are used for opening a circular strand of DNA at just one point. Other enzymes have a smaller recognition site, three or four bases long; these produce small fragments that can then be used to determine the sequence of bases along the DNA.

The cut that each enzyme makes varies from enzyme to enzyme. Some, like *Hin* dII, make a clean cut straight across the double helix, leaving DNA fragments with ends that are flush. Other enzymes (*Eco* RI) make a staggered break, leaving single strands with protruding cohesive ends ("sticky ends") that are complementary in base sequence. Following breakage, and under the right conditions, the complementary bases from different sources can be rejoined to form recombinant DNA.

Another important biochemical tool used by genetic engineers is DNA polymerase, an enzyme that normally catalyses the growth of a **nucleic acid** chain. DNA polymerase is used by genetic engineers to seal the gaps between the two sets of fragments in newly joined chimera molecules of recombinant DNA. DNA polymerase is also used to label DNA fragments, for DNA polymerase labels practically every base, allowing minute quantities of DNA to be studied in detail. If a piece of **ribonucleic acid** (RNA) of the target gene is the starting point, then the enzyme reverse transcriptase is used to produce a strand of complementary DNA (cDNA).

Genetic engineers usually need large numbers of genetically identical copies of the DNA fragment of interest. One way of doing this is to insert the gene into a suitable gene carrier, called a **cloning** vector. Common cloning vectors are bacterial plasmids or viruses such as the bacteriophage lambda, which are small circles of DNA found in bacterial cells independently of the main DNA molecule. When the cloning vectors divide, they replicate both themselves and the foreign DNA segment linked to it.

DNA injected into a mouse embryo. (Photograph by Jon Gordon. Phototake. Reproduced by permission.)

In the plasmid insertion method, restriction enzymes are used to cleave the plasmid double helix so that a stretch of DNA (previously cleaved with the same enzyme) can be inserted into the plasmid. As a result, the "sticky ends" of the plasmid DNA and the foreign DNA are complementary and base-pair when mixed together. The fragments held together by base pairing are permanently joined by DNA ligase. The host bacterium, with its 20- to 30-minute reproductive cycle, is like a manufacturing plant. With repeated doublings of its offspring on a controlled culture medium, millions of clones of the purified DNA fragments can be produced overnight.

Similarly, if viruses (bacteriophages) are used as cloning vectors, the gene of interest is inserted into the phage DNA, and the **virus** is allowed to enter the host bacterial cell where it multiplies. A single parental lambda phage particle containing recombinant DNA can multiply to several hundred progeny particles inside the bacterial cell (*E. coli*) within roughly 20 minutes.

Cosmids are another type of viral cloning vehicle that attaches foreign DNA to the packaging sites of a virus and thus introduces the foreign DNA into an infective viral particle. Cosmids allow researchers to insert very long stretches of DNA into host cells where cell multiplication amplifies the amount of DNA available. Large artificial chromosomes of yeast (called megaYACs) are also used as cloning vehicles, since they can store even larger pieces of DNA, 35 times more than can be stored conventionally in bacteria.

The polymerase **chain reaction** (PCR) technique is an important new development in the field of genetic engineering, since it allows the mass production of short segments of DNA directly, and offers the advantage of bypassing the several steps involved in using bacterial and viruses as cloning vectors.

DNA fragments can be introduced into mammalian cells, but a different method must be used. Here, genes packed in solid calcium phosphate are placed next to a cell membrane that surrounds the fragment and transfers it to the cytoplasm. The gene is delivered to the nucleus during mitosis (when the nuclear membrane has disappeared) and the DNA fragments are incorporated into daughter nuclei, then into daughter cells. A mouse containing human **cancer** genes (the onchomouse) was patented in 1988.

The potential benefits of recombinant DNA research are enormous. In recent years, scientists have identified the genetic basis of a number of medical disorders. Genetic engineering helps scientists replace a particular missing or defective gene with correct copies of that gene. If that gene then begins functioning in an individual, a genetic disorder may be cured. Researchers have already met with great success in finding the single genes that are responsible for common diseases like cystic **fibrosis** and hemochromatosis. In the early twenty-first century, scientists were applying knowledge from the human genome project to try to map multiple genes responsible for diseases like diabetes, hypertension, and schizophrenia.

Genetic engineering has also led to a great deal of controversy, however. Since scientists can duplicate genes, they can also duplicate, or "clone" animals and humans. In December 2001, scientists announced the birth of the first cloned female cat, although the 1990s saw big headlines for the first big mammal cloning of sheep. The announcement was made in April 2002 that the first human baby produced by a human cloning program would be born in November, sparking considerable medical and ethical controversy. In August 2001, President George W. Bush struggled with the debate over allowing federal funding for embryonic stem cell research. He allowed funding for only existing lines of cells, leaving further research in the hands of those who could seek private funding.

Genetic engineering also presents positive and negative controversy in its application to agriculture and the **environment**. Recombinant DNA techniques help scientists produce plants that offer medicinal value too. For example, calcium-fortified orange juice or vitamin-enriched milk boost the nutritional value of these foods. However, scientists can now further genetically modify foods, offering benefits and risks to the environment. The benefits mean possible cheaper and easier production of certain medicines, while the risks include unnatural introduction of plants and animals produced in a laboratory environment. At the University of Arizona, scientists have modified tomatoes to produce vaccines for diarrhea and hepatitis B, and that these vaccines will likely be much cheaper to produce than current drugs. Some critics worry that once the new crops move out of the safety of locked greenhouses and into crop fields, them may cross-pollinate with conventional tomato crops and contaminate them with modified genes.

A poll reported on in 2002 showed that Americans were fairly evenly split on their feelings about the risks and benefits of genetically modified foods and **biotechnology**. Most like the idea that scientists can create plants that will help clean up toxic soils, reduce **soil erosion** and reduce **fertilizer** run-off into streams and lakes. They also favor production of genetically engineered methods to reduce the amount of water used to grow crops and development of disease-resistant tree varieties to replace those that might be threatened or endangered. Americans also favor use of genetic engineering to reduce the need to log in native forests and to reduce the amount of chemical pesticides used by farmers. On the other hand, Americans express concern over possible environmental effects of genetically modified plants or fish contaminating ordinary plants and fish, reducing genetic diversity, increasing the number of insects that might become resistant to pesticides, or changing the **ecosystem**. *See also* Gene bank; Gene pool

Genetic resistance (or genetic tolerance)

Genetic **resistance** (or genetic tolerance) refers to the ability of certain organisms to endure environmental conditions that are extremely stressful or lethal to non-adapted individuals of the same **species**. Such tolerance has a genetic basis, and

it evolves at the population level in response to intense selection pressures.

Genetic resistance occurs when genetically variable populations contain some individuals that are relatively tolerant of an exposure to some environmental factor, such as the presence of a high concentration of a specific chemical. If the tolerance is genetically based (i.e., due to specific information embodied in the DNA of the organism's chromosomes), some or all of the offspring of these individuals will also be tolerant. Under conditions in which the chemical occurs in concentrations high enough to cause toxicity to non-tolerant individuals, the resistant ones will be relatively successful. As time passes their offspring will become increasingly more prominent in the population. Acquiring genetic resistance is an evolutionary process, involving increased tolerance within a population, for which there is a genetic basis, and occurring in response to selection for resistance to the effects of a toxic chemical. Some of the best examples of genetic resistance involve the tolerance of certain bacteria to antibiotics and of certain pests to pesticides.

Resistance to antibiotics

Antibiotics are **chemicals** used to treat bacterial infections of humans and domestic animals. Examples of commonly used antibiotics include various kinds of penicillins, streptomycins, and tetracyclines, all of which are metabolic byproducts created by certain **microorganisms**, especially **fungi**. There are also many synthetic antibiotics.

Antibiotics are extremely toxic to non-resistant strains of bacteria, and this has been very beneficial in the control of bacterial infections and diseases. However, if even a tiny fraction of a bacterial population has a genetically based tolerance to a specific antibiotic, **evolution** will quickly result in the development of a population that is resistant to that chemical. Bacterial resistance to antibiotics was first demonstrated for penicillin, but the phenomenon is now quite widespread. This is an important medical problem because some serious pathogens are now resistant to virtually all of the available antibiotics, which means that infections by these bacteria can be extremely difficult to control. Bacterial resistance has recently become the cause of infections by some virulent strains of *Staphylococcus* and other potentially deadly bacteria. Some biologists believe that this problem has been made worse by the failure of many people to finish their course of prescribed antibiotic treatments, which can allow tolerant bacteria to survive and flourish. Also possibly important has been the routine use of antibiotics to prevent diseases in livestock kept under crowded conditions in industrial farming. The small residues of antibiotics in meat, eggs, and milk may be resulting in low-level selection for resistant bacteria in exposed populations of humans and domestic animals.

Resistance to Pesticides

The insecticide **dichlorodiphenyl-trichloroethane** (DDT) was the first **pesticide** to which insect pests developed resistance. This occurred because the exposure of insect populations to toxic DDT results in intense selection for resistant genotypes. Tolerant populations can evolve because genetically resistant individuals are not killed by the pesticide and therefore survive to reproduce. Almost 500 species of insects and mites have populations that are known to be resistant to at least one insecticide. There are also more than 100 examples of fungicide-resistant plant pathogens and about 50 herbicide-resistant weeds. Insecticide resistance is most frequent among species of flies and their relatives (order Diptera), including more than 50 resistant species of malaria-carrying *Anopheles* mosquitoes. In fact, the progressive evolution of insecticide resistance by *Anopheles* has been an important factor in the recent resurgence of **malaria** in countries with warm climates. In addition, the protozoan *Plasmodium*, which actually causes malaria, has become resistant to some of the drugs that used to effectively control it.

Crop geneticists have recently managed to breed varieties of some plant species that are resistant to glyphosate, a commonly used agricultural **herbicide** that is effective against a wide range of weeds, including both monocots and dicots. The development of glyphosate-tolerant varieties of such crops as rapeseed means that this effective herbicide can be used to control difficult weeds in planted fields without causing damage to the crop.

Genetically engineered organism

The modern science of genetics began in the mid-nineteenth century with the work of Gregor Mendel, but the nature of the gene itself was not understood until James Watson and Francis Crick announced their findings in 1953. According to the Watson and Crick model, genetic information is stored in molecules of DNA (**deoxyribose nucleic acid**) by means of certain patterns of **nitrogen** base that occur in such molecules. Each set of three such nitrogen bases were

codes, they said, for some particular amino **acid**, and a long series of nitrogen bases were codes for a long series of amino acids or a protein.

Deciphering the genetic code and discovering how it is used in cells has taken many years of work since that of Watson and Crick. The basic features of that process, however, are now well understood. The first step involves the construction of a RNA (**ribonucleic acid**) molecule in the nucleus of a cell, using the code stored in DNA as a template. The RNA molecule then migrates out of the nucleus to a ribosome in the cell cytoplasm. At the ribosome, the sequence of nitrogen bases stored in RNA act as a map that determines the sequence of amino acids to be used in constructing a new protein.

This knowledge is of critical importance to biologists because of the primary role played by proteins in an organism. In addition to acting as the major building materials of which cells are made, proteins have a number of other crucial functions. All hormones and enzymes, for example, are proteins, and therefore nearly all of the chemical reactions that occur within an organisms are mediated by one protein or another.

Our current understanding of the structure and function of DNA makes it at least theoretically possible to alter the biological characteristics of an organism. By changing the kind of nitrogen bases in a DNA molecule, their sequence, or both, a scientist can change the genetic instructions stored in a cell and thus change the kind of protein produced by the cell.

One of the most obvious applications of this knowledge is in the treatment of genetic disorders. A large majority of genetic disorders occur because an organism is unable to correctly manufacture a particular protein molecule. An example is Lesch-Nyhan syndrome. It is a condition characterized by self-mutilation, mental retardation, and cerebral palsy which arises because a person's body is unable to manufacture an **enzyme** known as hypoxanthine guanine phosphoribosyl transferase (HPRT).

The general principles of the techniques required to make such changes are now well understood. The technique is referred to as **genetic engineering** or genetic surgery because it involves changes in an organism's gene structure. When used to treat a particular disorder in humans, the procedure is also called human gene therapy. Developing specific experimental techniques for carrying out genetic engineering has proved to be an imposing challenge, yet impressive strides have been made. A common procedure is known as recombinant DNA (rDNA) technology.

The first step in an rDNA procedure is to collect a piece of DNA that carries a desired set of instructions. For a genetic surgery procedure for a person with Lesch-Nyhan syndrome, a researcher would need a piece of DNA that codes for the production of HPRT. That DNA could be removed from the healthy DNA of a person who does not have Lesch-Nyhan syndrome, or the researcher might be able to manufacture it by chemical means in the laboratory.

One of the fundamental tools used in rDNA technology is a closed circular piece of DNA found in bacteria called a plasmid. Plasmids are the vehicle or vector that scientists use for transferring new pieces of DNA into cells. The next step in an rDNA procedure, then, would be to insert the correct DNA into the plasmid vector. Cutting open the plasmid can be accomplished using certain types of enzymes that recognize specific base sequences in a DNA molecule. When these enzymes, called restriction enzymes, encounter the recognized sequence in a DNA molecule, they cleave the molecule. After the plasmid DNA has been cleaved and the correct DNA mixed with it, a second type of enzyme is added. This kind of enzyme inserts the correct DNA into the plasmid and closes it up. The process is known as gene splicing.

In the final step, the altered plasmid vector is introduced into the cell where it is expected to function. In the case of a Lesch-Nyhan patient, the plasmid would be introduced into the cells where it would start producing HPRT from instructions in the correct DNA. Many technical problems remain with rDNA technology, and this last step has caused some of the greatest obstacles. It has proven very difficult to make introduced DNA function. Even when the plasmid vector with its new DNA gets into a cell, it may never actually begin to function.

Any organism whose cells contain DNA altered by this or some other technique is called a genetically engineered organism. The first human patient with a genetic disorder who is treated by human gene therapy will be a genetically engineered organism. The use of genetic engineering on human subjects has gone forward very slowly for a number of reasons. One reason is that humans are very complex organisms. Another reason is that changing the genetic make-up of a human involves more ethical questions and more difficult questions than does the genetic engineering of bacteria, mice, or cows.

Most of the existing examples of genetically engineered organisms, therefore, involve plants, non-human animals, or **microorganisms**. One of the earliest success stories in genetic engineering involved the altering of DNA in microorganisms to make them capable of producing **chemicals** they do not normally produce. Recombinant DNA technology can be used, for instance, to insert the DNA segment or gene that codes for insulin production into bacteria. When these bacteria are allowed to grow and reproduce in large fermentation tanks, they produce insulin. The list of chemicals produced by this mechanism now includes somatostatin, alpha interferon, tissue plasminogen activator

(tPA), Factor VIII, erythroprotein, and human growth hormone, and this list continues to grow each year.

Genetically modified organism

A genetically modified organism, or GMO, is an organism whose genetic structure has been altered by incorporating a single gene or multiple genes—from another organism or species—that adds, removes, or modifies a trait in the organism by a technique called gene splicing. An organism that has been genetically modified—or engineered—to contain a gene from another **species** is also called a transgenic organism (because the gene has been transferred) or a living modified organism (LMO). Most often the transferred gene allows an organism—such as a bacterium, fungus, **virus**, plant, insect, fish, or mammal—to express a trait that enhances its desirability to producers or consumers of the final product.

Overview

Plants and livestock have been bred for desired qualities (selective breeding) for thousands of years—long before people knew anything about the science of genetics. As technology advanced, however, so did the means by which people could select desired traits. Modern **biotechnology** represents a significant step in the history of genetic modification.

Until the final decades of the twentieth century, breeding techniques were limited to the transfer of desired traits within the same or closely related species. Genetically modified organisms, however, may contain traits transferred from completely dissimilar species. For example, before modern biotechnology, apple breeders could only cross-breed apples with apples or other closely related species. So, if a breeder wanted to make a certain tasty apple variety that was more tolerant to the cold, a cold-tolerant apple variety had to be hybridized with a tasty variety. This process usually involved significant trial and error because there was little assurance the cold-tolerance ability would be transferred in any individual attempt to hybridize the two varieties.

Development of modern biotechnology

The characteristics of all organisms are determined by genes—the basic units of heredity. A gene—a segment of deoxyribonucleic **acid** (DNA)—is capable of replication and **mutation**, occupying a fixed position on a chromosome (a group of several thousand genes; humans are defined by 22 pairs of chromosomes plus X and Y), and is passed on from parents to offspring during reproduction. A gene determines the structure of a protein or a **ribonucleic acid** (RNA) molecule. Found in all cells, DNA carries the genetic instructions for creating proteins; RNA decodes those instructions. Proteins perform diverse biological functions in the body, from helping muscles contract, to enabling blood to clot, to allowing biochemical reactions to proceed quickly enough to sustain life. By modifying a protein, particular phenotypic (physical) or physiologic changes—such as the color of a rose or the ability to bioluminesce (glow like a firefly)—are created.

A fundamental aspect of modern biotechnology is the belief that the essential genetic elements of all life are the same. Since the 1950s, molecular biologists have known that the DNA in every organism is made up of pairs of four nitrogen-containing bases, or building blocks: adenine (A), thymine (T), cytosine (C), and guanine (G).

In 1953, scientists James Watson and Francis Crick discovered that DNA is constructed in a double helix pattern—sort of a twisted ladder. Although A always pairs with T, and G with C, there is significant variety in how the pairs stack. The variable sequence of these DNA base pairs constitutes, in effect, the variety of life. So even all organisms are made from the same basic building blocks, their differences are a result of varying DNA sequences. A principle of modern molecular biology and biotechnology is that because these genetic building blocks are the same for all species, DNA can be extracted and inserted across species.

Genetic engineering techniques

The tools of modern biotechnology allow the transfer of specific genes, hence specific traits, to occur with more **precision** than ever before. The individual gene conveying a trait can be identified, isolated, replicated, and the inserted into another organism. This process is called **genetic engineering**, or recombinant DNA (rDNA) technology—that is, recombining DNA from multiple organisms.

Through such engineering, the apple breeder who wants the tasty apple variety to be cold-tolerant as well has the potential to find a gene that conveys cold tolerance and insert that gene directly into the tasty variety. Although

there is still some trial and error in this process, overall, there is greater precision in the ability to move genes from one organism to another. The gene that conveys a cold-tolerance ability does not need to come from another apple variety; it may come from any other organism. A cold-tolerant fish, for example, might have a suitable gene.

There are multiple methods by which genetic material may be transferred from one organism to another. Before a gene is moved between organisms, however, it is necessary to identify the individual gene that confers the desired trait. This stage is often quite time-consuming and difficult because often it is not clear what gene is needed or where to find it. Finding the gene entails using or creating a library of the species' DNA, specifying the amino acid sequence of the desired protein, and then devising a probe (any biochemical agent labeled or tagged in some way so that it can be used to identify or isolate a gene, RNA, or protein) for that sequence. As of 2002, isolating the desired gene is one of the most limiting aspects to creating a GMO.

Once the desired gene has been identified it must be extracted from the organism, which is usually done with a restriction endonuclease (an **enzyme**). Restriction endonucleases recognize particular base sequences in a DNA molecule and cut and isolate these sequences in a predictable and consistent manner. Once isolated, the gene must be replicated to generate sufficient usable material, as more than one copy of the gene is needed for the next steps in the engineering process.

One common method of gene replication is called polymerase **chain reaction** (PCR). Through the PCR method, the strands of the DNA are broken apart—in effect, the ladder is divided down the middle—and then exact copies of the opposite sides of the ladder are produced, creating thousands or millions of copies of the complete gene.

After replication, the gene must be inserted into the new organism via a vector (an agent that transfers material—typically DNA—from one host to another). A common vector is *Agrobacterium tumefaciens*, a bacterium that normally inserts itself into plants, causing a tumor. By genetically engineering *A. tumefaciens*, however, the bacterium can be used to insert the desired gene into a plant, replacing its tumor-causing genetic material.

Another vector, called ballistics, involves coating a microprojectile—usually a heavy metal such as tungsten—with the desired gene, then literally shooting the microprojectile into material from the new host organism. The microprojectile breaks apart the DNA of the host organism. Then when the DNA reassembles, some of the new, desired genetic material is inserted. Once the DNA has been inserted, the host organism can be grown, raised, or produced normally and tests can be performed to observer whether the desired trait manifests.

Varieties of GMOs

In 2000, of the total land planted with GMO crops worldwide, the United States occupied 68%, Argentina 23%, and China 1%. The United States produces many types of GMOs for commercial and research purposes.

Agricultural crops

A common type of GMO is the modified agricultural seed. Corn, soybeans, and cotton are a few examples of staple agricultural GMO products grown in the United States. Genetic modifications to these products may, for example, alter a crop's nutritional content, storage ability, or taste.

With the advent of genetic engineering, for example, common hybrid crops such as the tomato were launched into a new era. The first food produced from gene splicing and evaluated by the **Food and Drug Administration** (FDA) was the Flavr Savr Tomato in 1994. Tomatoes usually get softer as they ripen because of a protein in the tomato that breaks down the cell walls of the tomato. Because it is difficult to ship a quality ripe tomato across the country before the tomato spoils, tomatoes are usually shipped unripened. Engineers of the Flavr Savr Tomato spliced a gene into its deoxyribonucleic acid (DNA) to prevent the breakdown of the tomato's cell walls. The result of adding the new gene was a firm ripe tomato that was more desirable to consumers than the tasteless variety typically found on store shelves, particularly in the winter months.

Genetic modifications may also confer to a species an ability to produce its own **pesticide** biologically, thereby potentially reducing or even eliminating the need to apply external pesticides. For example, ***Bacillus thuringiensis*** (Bt) is a soil bacterium that produces toxins against insects (mainly in the genera *Lepidoptera*, *Diptera*, and *Coleoptera*).- When they are genetically modified to carry genetic material from the Bt bacterium, plants such as soybeans will able to produce their own Bt toxin and be resistant to insects such as the cornstalk borer and velvetbean catepillar. Researchers at the Monsanto chemical company estimate that Bt soybeans will be commercially available by about 2006.

By means of genetic engineering, a gene from a soil bacterium called *Agrobacterium* sp confers glyphosate **resistance** to a plant. Glyphosate (brand names include Roundup, Rodeo, and Accord) is a broad-spectrum **herbicide** (kills all green plants). As of 2002, Monsanto was the sole developer of all glyphosate resistant crops on the market. These crops (often called "Roundup Ready") include corn, soybeans, cotton, and canola.

Pharmaceuticals

Genetically engineered pharmaceuticals are also useful GMO products. One of the first GMOs was a bacterium with a human gene inserted into its genetic code to produce a very high quality human insulin for diabetes. Vaccines

against diseases such as meningitis or hepatitis B, for example, are produced by genetically engineered yeast or bacteria. Other pharmaceuticals produced by using GMO **microbes** include interferon for **cancer**, erythropoetin for **anemia**, growth hormone for the treatment of dwarfism, tissue plasminogen activator for heart attack victims. Through genetic engineering, transgenic plants are likely to become a commercially viable source of pharmaceuticals.

Benefits and risks

Although the technological advances that allowed the creation of GMOs are impressive, as with any new technology, the benefits must be weighed against the risks. Useful pharmaceutical products have been created as a result of genetic engineering. Also, GMOs have produced and new and improved agricultural products that are resistant to crop pests, thus improving production and reducing chemical pesticide usage. These developments have had a major impact on food quality and nutrition.

The possibility that biotech crops could make a substantial contribution to providing sufficient food for an expanding world is also a reason given for engaging in the research that underlies their development. However, the debate over GMOs continues among scientists and between consumers and modern agricultural producers throughout the world regarding issues such as regulation, labelling, human health risk, and environmental impact.

In the United States, for example, there has been much controversy over the health risks of canola oil. Canola oil is genetically engineered rapeseed oil or "LEAR" oil (low erucic acid rape), a semi-drying industrial oil used as a lubricant, fuel, soap, and synthetic **rubber** base, and as an illuminant to give color pages in magazines their slick look. It was first developed in Canada (thus the name "canola oil").

Canola oil is derived from the mustard family and is considered a toxic and poisonous weed. In 1998, the EPA classified canola oil as a biopesticide with "low chronic toxicities," yet placed it on the "Generally Considered Safe" list of foods. Proponents, who tout the oil's health benefits, claim that due to genetic engineering and irradiation, it is completely safe, pointing to its unsaturated structure and digestibility.

Widely used as a cooking oil, and because it is so inexpensive, it is used in thousands of processed foods in the United States and North America. Thus, millions of people have been exposed—most of them unknowingly—to genetically engineered foods. However, there has been little research on the potential adverse effects of these products on humans.

When processed, canola oil becomes rancid very easily. It has been shown to cause health problems such as lung cancer and has been associated with loss of vision, disruption of the central nervous system, respiratory illness, anemia, constipation, increased incidence of heart disease and cancer, low birth weight in infants, and irritability. It has a tendency to inhibit proper **metabolism** of foods and curbs normal enzyme function. Generally, rapeseed has a cumulative effect, often taking nearly ten years for symptoms to manifest.

The dangers of introducing genes that may cause undesirable effects in the **environment** is also a concern among many. For example, when farmers spray an herbicide to remove weeds growing among crops, the sprayed chemical often damages the crop plants. If the crop is genetically engineered to be resistant to the chemical, the weeds are killed, but the crop plants remain undamaged.

Although this situation appears to be beneficial, it is likely to lead to greater use of the particular herbicide, which would have several negative effects: the crop is likely to contain greater herbicide residues; and the increased spraying contaminates the rest of the environment. Although not all herbicides are dangerous, the safer choice seems to minimize rather than maximize their use. Also, if genes added to produce pesticide resistance in crop plants jumped to a weed species, then weeds would thrive and be difficult to control.

Thus, as debate over GMOs rages, it is important to note that a wide variety of ecological and human health concerns exist side by side with the new advances made possible by genetic engineering.

Geodegradable

The term geodegradable refers to a material that could degrade in the **environment** over a geologic time period. While **biodegradable** generally refers to items that may degrade within our lifetime, geodegradable material does not decompose readily and may take hundreds or thousands of years. **Radioactive waste**, for example, is degraded only over thousands of years. The glass formed as an end result of a **hazardous waste** treatment technology known as "in situ vitrification," is considered geodegradable only after a million years. *See also* Half-life; Hazardous waste site remediation; Hazardous waste siting; Waste management

Geographic information systems

A Geographic Information System (GIS) is a computer system capable of assembling, storing, mapping, **modeling**, manipulating, querying, analyzing, and displaying geographically referenced information (i.e., data that are identified according to their locations). Some practitioners expand the definition of GIS to include the personnel involved, the data that are entered into the system, and the uses, decisions, and interpretations that are made possible by the system. A GIS can be used for scientific investigations, resource management, and planning. The development of GIS was made possible from innovations in many different disciplines, including geography, cartography, remote sensing, surveying, civil engineering, **statistics**, computer science, operations research, artificial intelligence, and demography.

Even early man used GIS-type systems. Thirty-five thousand years ago Cro-Magnon hunters in Lascaux, France, drew pictures of the animals they hunted. Along with the animal drawings were track lines that are thought to show **migration** routes. These early records included two essential elements of modern GIS: a graphic file linked to an attribute data base.

In a GIS, maps and other data from many different sources and in many different forms are stored or filed as layers of information. A GIS makes it possible to link and integrate information that is difficult to associate through other means. A GIS can combine mapped variables to build and analyze new variables. For example, by knowing and entering data for water use for a specific residence, predictions can be made on the amount of **wastewater** contaminants generated and released to the **environment** from that residence.

The primary requirement for the source data is that the locations for the variables are known. Any variable that can be located spatially can be entered into a GIS. Location may be determined by x, y, and z coordinates of longitude, latitude, and elevation, or by other systems such as ZIP codes or highway mile markers. A GIS can convert existing digital information, which may not be in map form, into forms it can recognize and utilize. For example, census data can be converted into map form, such that different types of information can be presented in layers.

If data are not in digital form, (i.e., not in a form that the computer can utilize), various techniques are available to capture the information. Maps can be hand traced with a computer mouse to collect the coordinates of features. Electronic scanning devices can be used to convert map lines and points to digits. Data capture, i.e., entering the information into the system, is the most time-consuming component of a GIS. Identities of the objects on the map and their spatial relationships must be specified. Editing of information that is captured can be difficult. For example, an electronic scanner will record blemishes on a map just as it will record actual map features. A fleck of dirt that is scanned may connect two lines that should not be connected. Such extraneous information must be identified and removed from the digital data file.

Different maps may be at different scales, so map information in a GIS must be manipulated so that it fits with information collected from other maps. Data may also have to undergo projection conversion before being integrated into a GIS. Projection, a fundamental component of map making, is a mathematical means of transferring information from the earth's three-dimensional curved surface to a two-dimensional medium (i.e., paper or a computer screen). Different projections are used for different types of maps based on the type of projection appropriate for a specific use. Much of the information in a GIS comes from existing maps, so the computing power of the GIS can integrate digital information from different sources with different projections into a common projection.

Digital data are collected and stored in various ways, and so different data sources may not be compatible. A GIS must be able to convert data from one structure to another. For example, image data from a satellite that has been interpreted by a computer to produce a **land use** map can be entered into the GIS in raster format. Raster format is like a spreadsheet, with rows and columns into which numbers are placed. These rows and columns are linked to x,y coordinates, with the intersection of each row and column forming a cell that corresponds to a specific point in the world. These cells contain numbers that can represent such features as elevation, soils, archeological sites, etc. Maps in a raster GIS can be handled like numbers (e.g., added, subtracted, etc.) to form new maps. Raster data files can be quickly manipulated by computer but are less detailed and may be less visually appealing than vector data files, which appear more like traditional hand-drafted maps. Vector digital data are

captured as points, lines (a series of point coordinates), or areas (shapes bounded by lines). A Vector GIS output looks more like a traditional paper map.

A GIS can be used to depict two- and three-dimensional characteristics of the earth's surface, subsurface, and **atmosphere** from information points. Each thematic map (i.e., a map displaying information about one characteristic of a region) is referred to as a layer, coverage, or level. A specific thematic map can be overlain and analyzed with any other thematic map covering the same area. Not all analyses may require using all of the map layers at the same time. A researcher may use information selectively to consider relationships among specific layers. Information from two or more layers may be combined and transformed into a new layer for use in subsequent analyses. For example, with maps of **wetlands**, slopes, streams, land use, and soils, a GIS can produce a new overlay that ranks the wetlands according to the relative sensitivity to damage from nearby factories or homes. This process of combining and transforming information from different layers is referred to as map "algebra," as it involves adding and subtracting information.

Recorded information from off-screen files can be retrieved from the maps by pointing at a location, object, or area on the screen. Conditions of adjacency (what is next to what) containment (what is enclosed by what), and proximity (how close something is to something else) can be determined using a GIS.

A GIS can also be used for "what if" scenarios by simulating the route of materials along a linear network. For example, an evaluation could be made on how long it would take for **chemicals** accidentally released into a river from a factory to move into a wetland area. Direction and speed can be assigned to the digital stream, and the contaminants can be traced through the stream system.

An important component of a GIS is the ability to produce graphics on the computer screen or to output to paper (e.g., wall maps) to inform resource decision makers about the results of analyses. The viewers of such materials can visualize and thus better understand the results of analyses or simulations of potential events. A GIS can be used to produce not only maps, but also drawings and animations that allow different ways of viewing information. These types of images are especially helpful in conveying technical concepts to non-scientists.

GIS technology is an improvement in the efficiency and analytical power of cartographic science. Traditional maps are abstractions of the real world, with important elements portrayed on a sheet of paper with symbols to represent physical objects. For example, topographic maps show the shape of the land surface with contour lines, but the actual shape of the land can only be imagined. Graphic display techniques in a GIS illustrate more clearly relationships among the map elements, increasing the ability to extract and analyze information.

Many commercial GIS software systems are available, some of which are specialized for use in specific types of decision-making situations. Other programs are more general and can be used for a wide number of applications or can be customized to meet individual requirements.

GIS applications are useful for a wide range of disciplines, including urban planning, environmental and natural resource management, facilities management, **habitat** studies, archaeological analyses, hazards management, emergency planning, marketing and demographic analyses, and **transportation** planning. The ability to separate information in layers and then combine the layers with other layers of information is the key to making GIS technology a valuable tool for the analysis and display of large volumes of data, thus allowing better management and understanding of information and increased scientific productivity.

Geological Survey

The United States Geological Survey (USGS) is the federal agency responsible for surveying and publishing maps of **topography** (giving landscape relief and elevation), geology, and natural resources—including minerals, fuels, and water. The USGS, part of the U. S. Department of the Interior, was formed in 1879 as the United States began systematically to explore its newly expanded western territories. Today it has an annual budget of about $700 million, which is devoted to primary research, resource assessment and monitoring,

map production, and providing information to the public and to other government agencies.

The United States Geological Survey, now based in Reston, Virginia, originated in a series of survey expeditions sent to explore and map western territories and rivers after the Civil War. Four principal surveys were authorized between 1867 and 1872: Clarence King's exploration of the fortieth parallel, Ferdinand Hayden's survey of the Rocky Mountain territories, John Wesley Powell's journey down the **Colorado River** and through the Rocky Mountains, and George Wheeler's survey of the 100th meridian. Twelve years later, in 1879, these four ongoing survey projects were combined to create a single agency, the United States Geological Survey. The USGS' first director was Clarence King. In 1881 his post was taken by John Wesley Powell, whose name is most strongly associated with the early Survey. It was Powell who initiated the USGS topographic mapping program, a project that today continues to produce the most comprehensive map series available of the United States and associated territories.

In addition to topographic mapping, the USGS began detailed surveys and mapping of mineral resources in the 1880s. Mineral exploration led to mapping geologic formations and structures and a gradual reconstruction of geologic history in the United States. Research and mapping of glacial history and fossil records naturally followed from mineral explorations, so that the USGS became the primary body in the United States involved in geologic field research and laboratory research in experimental geophysics and geochemistry. During World Wars I and II, the USGS' role in identifying and mapping tactical and strategic resources increased. Water and fuel resources (**coal**, oil, **natural gas**, and finally **uranium**) were now as important as **copper**, gold, and mineral ores, so the Survey took on responsibility for assessing these resources as well as topographic and geologic mapping.

Today the USGS is one of the world's largest earth science research agencies and the United States' most important map publisher. The Survey conducts and sponsors extensive laboratory and field research in geology, **hydrology**, oceanography, and cartography. The agency's three divisions, **Water Resources**, Geology, and National Mapping, are responsible for basic research. They also publish, in the form of maps and periodic written reports, information on the nation's topography, geology, fuel and mineral resources, and other aspects of earth sciences and **natural resources**. Most of the United States' hydrologic records and research, including streamflow rates, **aquifer** volumes, and **water quality**, are produced by the USGS. In addition, the USGS publishes information on natural hazards, including earthquakes, volcanoes, landslides, floods, and droughts. The Survey is the primary body responsible for providing basic earth science information to other government agencies, as well as to the public. In addition, the USGS undertakes or assists research and mapping in other countries whose geologic survey systems are not yet well developed.

Georges Bank (collapse of the ground fishery)

Until the 1990s Georges Bank, off the coasts of New England and Nova Scotia, was one of the world's most valuable fisheries. A bank is a plateau found under the surface of shallow ocean water. Georges Bank is the southernmost and the most productive of the banks that form the continental shelf. A majority of the $800 million northeastern fishery industry comes from Georges Bank. The oval shaped bank is 149 mi long and 74.5 mi wide (240 km by 120 km). Georges Bank covers an area larger than the state of Massachusetts. The ocean bottom of Georges Bank formed ideal **habitat** for favorable quantities of groundfish, *demersal finfishes*, fish which feed off or near the ocean's floor mdash; cod, *Gadidae*, clam, *Pelecypoda*, haddock, *Melanogrammus aeglefinus*, hake, *Merlucciidae*, herring, *Clupea harengus*, lobster, *Homarus*, pollock, *Pollachaius*, flounder, and scallops, *Pectinidae*. But by 1994 the Georges Bank ground fishery had collapsed.

Cod were by far the most numerous and valuable of the Georges Bank's fish. Atlantic cod form distinct stocks and the Georges Bank stock grows faster than those of the colder waters further north. They are the world's largest and thickest cod. In 1938 a cod weighing 180 lb (82 kg) was caught off the bank. The cod move in schools from feeding to spawning grounds, in dense aggregates of hundreds of millions of fish, making them easy prey for fishing nets.

During the second half of the twentieth century, gigantic trawlers towing enormous nets could haul in 200 tons (181.4 metric tons) of fish an hour off Georges Bank. At its peak in 1968, 810,000 tons (734,827 metric tons) of cod were harvested. By the 1970s, fleets of Soviet, European, and Japanese factory ships were trawling the cod-spawning grounds, scooping up the fish before they could reproduce. If the catch was of mixed **species** or the wrong size, the nets were dumped, leaving the ocean surface teaming with dead fish. After the catch was sorted, many species of dead

bycatch, including young cod, flounder, and crabs, were discarded. For every three tons of processed fish, at least a ton of bycatch died. These ships also trawled for herring, capelin, mackerel, and other small fish that the cod and other groundfish depend on for food.

The Fisheries Conservation and Management Act of 1976 extended exclusive American fishing rights from 12–200 mi (19–322 km) offshore. Since much of Georges Bank is within the 200-mi (322 km) limit of Nova Scotia, conflict erupted between American and Canadian fishermen. International arbitration eventually gave Canada the northeast corner of the bank. The legislation also established the New England Fishery Management Council to regulate fishing. Although the goal was to conserve fisheries as well as to create exclusive American fishing grounds, the council was controlled by commercial interests. The result was the development of financial incentives and boat-building subsidies to modernize the fishing fleet.

Soon the New England fleet surpassed the fishing capacities of the foreign fleets it replaced and every square foot of Georges Bank had been scraped with the heavy chains that hold down the trawling nets and stir up fish. This destroyed the rocky bottom structure of the bank and the vegetation and marine invertebrates that created habitat for the groundfish. Cod, pollack, and haddock were replaced by dogfish and skates, so-called "trash fish."

During the 1990s tiny hydroids, similar to jellyfish, began appearing off Georges Bank, in concentrations as high as 100 per gal of water. Although they were drifting in the water, they were in their sedentary life-stage form, indicating that they may have been ripped from their attachments by storms or commercial trawlers. These hydroids ate most of the small crustaceans that the groundfish larvae depend on. They also directly killed cod larvae.

In 1994 the National Marine Fisheries Service found that the Georges Bank cod stock had declined by 40% since 1990, the largest decline ever recorded. Furthermore, the yellowtail flounder stock had collapsed. In a given year, only eight out of 100 flounder survived and the breeding population had fallen 94% in three years. The last successful flounder spawning was in 1987; but 60% of the catch from that year's group were too small to sell and were discarded. In response the Fisheries Service closed large areas of Georges Bank, but fishing continued in the Canadian sector and western portions of the American sector. With the goal of annually harvesting only 15% of the remaining stock, each vessel was restricted to 139 days of ground fishing. Nevertheless by 1996, 55% of the remaining Georges Bank cod stock — the only surviving North Atlantic population — had been caught. Fishing was restricted to 88 days. A satellite-based vessel monitoring system is used to detect fishing boats that enter closed areas of Georges Bank.

At the time of the cod moratorium, it was argued that the population would recover in five years; however there were few signs of recovery as of 2002. Not only is the cod stock near an all-time low, but so are populations of other commercial fish and many other species. The average size of the bottom-dwelling fish of Georges Bank is a fraction of what it was twenty years ago.

Georges Bank is just one example of a eastern coastal area negatively affected by excessive trawling. Even though there is $800 million worth of fish extracted from Georges Bank and the surrounding area, there is an overall decline in groundfish stock along the entire boreal and sub-arctic coast of eastern North America. American and Canadian moratoriums on gas and oil exploration and extraction from Georges Bank—activities that could further disrupt the fishery—are in effect until at least 2012.

Geosphere

The solid portion of the earth. It is also known as the lithosphere. From a technical standpoint, the geosphere includes inner parts of the earth virtually inaccessible to human study, the inner and outer core and mantle, as well as the outermost crust. For the most part, however, environmental scientists are primarily interested in the relatively thin outer layer of the crust on which plants and animals live, in the ores and minerals that occur within the crust, and in the changes that take place in the crust as a result of **erosion** and mountain-building.

Geothermal energy

Geothermal energy is obtained from hot rocks beneath the earth's surface. The planet's core, which may generate temperatures as high as 8,000°F (4,500°C), heats its interior, whose temperature increases, on an average, by about 1°C (2°F) for every 60 ft (18 m) nearer the core. Some heat is also generated in the mantle and crust as a result of the **radioactive decay** of **uranium** and other elements.

In some parts of the earth, rocks in excess of 212°F (100°C) are found only a few miles beneath the surface. Water that comes into contact with the rock will be heated above its boiling point. Under some conditions, the water becomes super-heated, that is, is prevented from boiling even though its temperature is greater than 212°F (100°C). Regions of this kind are known as wet steam fields. In other situations the water is able to boil normally, producing steam. These regions are known as dry steam fields.

Humans have long been aware of geothermal energy. Geysers and fumaroles are obvious indications of water heated by underground rock. The Maoris of New Zealand, for example, have traditionally used hot water from geysers to cook their food. Natural hot spring baths and spas are a common feature of many cultures where geothermal energy is readily available.

The first geothermal well was apparently opened accidentally by a drilling crew in Hungary in 1867. Eventually, hot water from such **wells** was used to heat homes in some parts of Budapest. Geothermal heat is still an important energy source in some parts of the world. More than 99% of the buildings in Reykjavik, the capital of Iceland, are heated with geothermal energy.

The most important application of geothermal energy today is in the generation of electricity. In general, hot steam or super-heated water is pumped to the planet surface where it is used to drive a turbine. Cool water leaving the generator is then pumped back underground. Some water is lost by evaporation during this process, so the energy that comes from geothermal wells is actually non-renewable. However, most zones of heated water and steam are large enough to allow a geothermal mine to operate for a few hundred years.

A dry steam well is the easiest and least expensive geothermal well to drill. A pipe carries steam directly from the heated underground rock to a turbine. As steam drives the turbine, the turbine drives an electrical generator. The spent steam is then passed through a condenser where much of it is converted to water and returned to the earth.

Dry steam fields are relatively uncommon. One, near Larderello, Italy, has been used to produce electricity since 1904. The geysers and fumaroles in the region are said to have inspired Dante's *Inferno*. The Larderello plant is a major source of electricity for Italy's electric railway system. Other major dry steam fields are located near Matsukawa, Japan, and at Geysers, California. The first electrical generating plant at the Geysers was installed in 1960. It and companion plants now provide about 5% of all the electricity produced in California.

Wet steam fields are more common, but the cost of using them as sources of geothermal energy is greater. The temperature of the water in a wet steam field may be anywhere from 360–660°F (180–250°C). When a pipe is sunk into such a reserve, some water immediately begins to boil, changing into very hot steam. The remaining water is carried out of the reserve with the steam.

At the surface, a separator is used to remove the steam from the hot water. The steam is used to drive a turbine and a generator, as in a dry steam well, before being condensed to a liquid. The water is then mixed with the hot water (now also cooled) before being returned to the earth.

The largest existing geothermal well using wet steam is in Wairakei, New Zealand. Other plants have been built in Russia, Japan, and Mexico. In the United States, pilot plants have been constructed in California and New Mexico. The technology used in these plants is not yet adequate, however, to allow them to compete economically with fossil-fueled **power plants**.

Hot water (in contrast to steam) from underground reserves can also be used to generate electricity. Plants of this type make use of a binary (two-step) process. Hot water is piped from underground into a heat exchanger at the surface. The heat exchanger contains some low-boiling point liquid (the "working fluid"), such as a **freon** or isobutane. Heat from the hot water causes the working fluid to evaporate. The vapor then produced is used to drive the turbine and generator. The hot water is further cooled and then returned to the rock **reservoir** from which it came.

In addition to dry and wet steam fields, a third kind of geothermal reserve exists: pressurized hot water fields located deep under the ocean floors. These reserves contain **natural gas** mixed with very hot water. Some experts be-

lieved that these geopressurized zones are potentially rich energy sources although no technology currently exists for tapping them.

Another technique for the capture of geothermal energy makes use of a process known as hydrofracturing. In hydrofracturing, water is pumped from the surface into a layer of heated dry rock at pressures of about 7,000 lb/in^2 (500 kg/cm^2). The pressurized water creates cracks over a large area in the rock layer. Then, some material such as sand or plastic beads is also injected into the cracked rock. This material is used to help keep the cracks open.

Subsequently, additional cold water can be pumped into the layer of hot rock, where it is heated just as natural **groundwater** is heated in a wet or dry steam field. The heated water is then pumped back out of the earth and into a turbine-generator system. After cooling, the water can be re-injected into the ground for another cycle. Since water is continually re-used in this process and the earth's heat is essentially infinite, the hydrofracturing system can be regarded as a renewable source of energy.

Considerable enthusiasm was expressed for the hydrofracturing approach during the 1970s and a few experimental plants were constructed. But, as oil prices dropped and interest in **alternative energy sources** decreased in the 1980s, these experiments were terminated.

Geothermal energy clearly has some important advantages as a power source. The raw material—heated water and steam—is free and readily available, albeit in only certain limited areas. The technology for extracting hot water and steam is well developed from petroleum-drilling experiences, and its cost is relatively modest. Geothermal mining, in addition, produces almost no **air pollution** and seems to have little effect on the land where it occurs.

On the other hand, geothermal mining does have its disadvantages. One is that it can be achieved in only limited parts of the world. Another is that it results in the release of gases, such as **hydrogen** sulfide, **sulfur dioxide**, and ammonia, that have offensive odors and are mildly irritating. Some environmentalists also object that geothermal mining is visually offensive, especially in some areas that are otherwise aesthetically attractive. **Pollution** of water by **runoff** from a geothermal well and the large volume of cooling water needed in such plant are also cited as disadvantages.

At their most optimistic, proponents of geothermal energy claim that up to 15% of the United States' power needs can be met from this source. Lagging interest and research in this area over the past decade have made this goal unreachable. Today, no more than 0.1% of the nation's electricity comes from geothermal sources. Only in California is geothermal energy a significant power source. As an example, GeoProducts Corporation, of Moraga, California, has constructed a $60 million geothermal plant near Lassen **National Park** that generates 30 megawatts of power.

Until the government and the general public becomes more concerned about the potential of various types of alternative energy sources, however, geothermal is likely to remain a minor energy source in the country as a whole. *See also* Alternative fuels; Fossil fuels; Renewable resources; Water pollution

Giant panda

Today, the giant panda (*Ailuropoda melanoleuca*) is one of the best known and most popular large mammals among the general public. Although its existence was known long ago, having been mentioned in a 2,500-year-old Chinese geography text, Europeans did not learn of its existence until its discovery by a French missionary in 1869. The first living giant panda did not reach the Western Hemisphere until 1937. The giant panda, variously classified with the true bears or, often, in a family of its own, once ranged throughout much of China and Burma, but is now restricted to a series of 13 **wildlife** reserves totaling just over 2,200 mi^2 (5,700 km^2) in three central and western Chinese provinces. The giant panda population has been decimated over the past 2,000 years by **hunting** and **habitat** destruction. In the years since 1987, they have lost more than 30% of their habitat. Giant pandas are one of the rarest mammals in the world, with current estimates of their population size at about 1,000 individuals (150 in captivity). Today human pressure on giant panda populations has diminished, although **poaching** continues. Giant pandas are protected by tradition and sentiment, as well as by law in the Chinese mountain forest reserves. Despite this progress, however, IUCN—The World Conservation Union—and the U. S. **Fish and Wildlife Service** consider the giant panda to be endangered. Some of this species' unique requirements and habits do seem to put them in jeopardy.

The anatomy of the giant panda indicates that it is a carnivore, however, its diet consists almost entirely of bamboo, whose cellulose cannot be digested by the panda. Since the giant panda obtains so little **nutrient** value from the bamboo, it must eat enormous quantities of the plant each day, about 35 lb (16 kg) of leaves and stems, in order to satisfy its energy requirements. Whenever possible, it feeds solely on the young succulent shoots of bamboo, which, being mostly water, requires it to eat almost 90 lb (41 kg) per day. This translates into 10–12 hours per day that pandas spend eating. Giant pandas have been known to supplement their diet with other plants such as horsetail and pine bark, and they will even eat small animals, such as rodents, if they can catch them, but well over 95% of their diet consists of the bamboo plant.

Bamboo normally grows by sprouting new shoots from underground rootstocks. At intervals from 40 to 100 years, the bamboo plants blossom, produce seeds, then die. New bamboo then grows from the seed. In some regions it may take up to six years for new plants to grow from seed and produce enough food for the giant panda. Undoubtedly this has produced large shifts in panda population size over the centuries. Within the last quarter century, two bamboo flowerings have caused the starvation of nearly 200 giant pandas, a significant portion of the current population. Although the wildlife reserves contain sufficient bamboo, much of the vast bamboo forests of the past have been destroyed for agriculture, leaving no alternative areas to move to should bamboo blossoming occur in their current range.

Low **fecundity** and limited success in captive breeding programs in zoos does not bode well for replenishing any significant losses in the wild population. Although there are 150 pandas in captivity, only about 28% are breeding. In 1999, the first giant panda to live more than a few days was born in captivity. For the time being, the giant panda population appears stable, a positive sign for one of the world's scarcest and most popular animals.

Giardia. (Photograph by J. Paulin. Visuals Unlimited. Reproduced by permission.)

Giardia

Giardia is the genus (and common) name of a protozoan parasite in the phylum Sarcomastigophora. It was first described in 1681 by Antoni van Leeuwenhoek (called "The Father of Microbiology"), who discovered it in his own stool. The most common **species** is *Giardia intestinalis* (also called *lamblia*), which is a fairly common parasite found in humans. The disease it causes is called giardiasis.

The trophozoite (feeding) stage is easily recognized by its pear-shaped, bilaterally-symmetrical form with two internal nuclei and four pairs of external flagella; the thin-walled cyst (infective) stage is oval. Both stages are found in the upper part of the small intestine in the mucosal lining. The anterior region of the ventral surface of the troph stage is modified into a sucking disc used to attach to the host's abdominal epithelial tissue. Each troph attaches to one epithelial cell. In extreme cases, nearly every cell will be covered, causing severe symptoms. Infection usually occurs through drinking contaminated water. Symptoms include diarrhea, flatulence (gas), abdominal cramps, fatigue, weight loss, anorexia, and/or nausea and may last for more than five days. Diagnosis is usually done by detecting cysts or trophs of this parasite in fecal specimens.

Giardia has a worldwide distribution. It is more common in warm, tropical regions than in cold regions. Hosts include **frogs**, cats, dogs, beaver, muskrat, horses, and humans. Children as well as adults can be affected, although it is more common in children. It is highly contagious. Normal infection rate in the United States ranges from 1.5 to 20%. In one case involving scuba divers from the New York City police and fire fighters, 22–55% were found to be infected, presumably after they accidentally drank contaminated water in the local rivers while diving. In another case, an epidemic of giar-

diasis occurred in Aspen, Colorado, in 1965 during the popular ski season and 120 people were infected. Higher infection rates are common in some areas of the world, including Iran and countries in Sub-Saharan Africa.

Giardia can typically withstand sophisticated forms of **sewage treatment**, including **filtration** and **chlorination**. It is therefore hard to eradicate and may potentially increase in polluted lakes and rivers. For this reason, health officials should make concerted efforts to prevent contaminated feces from infected animals (including humans) from entering lakes used for drinking water.

The most effective treatment for giardiasis is the drug Atabrine (quinacrine hydrochloride). Adult dosage is 0.1 g taken after meals three times each day. Side effects are rare and minimal. *See also* Cholera; Coliform bacteria

Gibbons

Gibbons (genus *Hylobates*, meaning "dweller in the trees") are the smallest members of the ape family which also includes gorillas, **chimpanzees**, and orangutans. They spend most of their lives at the tops of trees in the jungle, eating leaves and fruit. They are extremely agile, swinging at speeds of 35 mph (56 km/h) with their long arms on branches to move from tree to tree. The trees can even be 50 ft (15 m) apart. They have no tails and are often seen walking upright on tree branches. Gibbons are known for their loud calls and songs, which they use to announce their territory and warn away others. They are devoted parents, raising usually one or two offspring at a time and showing extraordinary affection in caring for them. Conservationists and animal protectionists who have worked with gibbons describe them as extremely intelligent, sensitive, and affectionate.

Gibbons have long been hunted for food, for medical research, and for sale as pets and **zoo** specimens. A common method of collecting them is to shoot the mother and capture the nursing or clinging infant, if it is still alive. The **mortality** rate in collecting and transporting gibbons to areas where they can be sold is extremely high. This, coupled with the fact that their jungle **habitat** is being destroyed at a rate of 32 acres (13 ha) per minute, has resulted in severe depletion of their numbers.

A gibbon. (©Breck P. Kent/JLM Visuals. Reproduced by permission.)

Gibbons are found in southeast Asia, China, and India, and nine **species** are recognized. All nine species are considered endangered by the **U.S. Department of the Interior** and are listed in the most endangered category of the

Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). **IUCN—The World Conservation Union** considers three species of gibbon to be endangered and two species to be vulnerable. Despite the ban on international trade in gibbons conferred by listing in Appendix I of CITES, illegal trade in gibbons, particularly babies, continues on a wide scale in markets throughout Asia.

Lois Marie Gibbs (1951 –)

American environmentalist and community organizer

An activist dedicated to protecting communities from hazardous wastes, Lois Gibbs began her political career as a housewife and homeowner near the **Love Canal**, New York. She was born in Buffalo on June 25, 1951, the daughter of a bricklayer and a full-time homemaker. Gibbs was 21 and a mother when she and her husband bought their house near a buried dump containing hazardous materials from industry and the military, including wastes from the research and manufacture of chemical weapons.

From the time the first articles about Love Canal began appearing in newspapers in 1978, Gibbs has petitioned for state and federal assistance. She began when she discovered the school her son was attending had been built directly on top of the buried canal. Her son had developed epilepsy and there were many similar, unexplained disorders among other children at the school, yet the superintendent was refusing to transfer anyone. The New York State Health Department then held a series of public meetings in which officials appeared more committed to minimizing the community perception of the problem than to solving the problem itself. The governor made promises he was unable to keep, and Gibbs herself was flown to Washington to appear at the White House for what she later decided was little more than political grandstanding. In the book she wrote about her experience, *Love Canal: My Story*, Gibbs describes her frustration and her increasing disillusionment with government, as the threats to the health of both adults and children in the community became more obvious and as it became clearer that no one would be able to move because no one could sell their homes.

While state and federal agencies delayed, the media took an increasing interest in their plight, and Gibbs became more involved in political action. To force federal action, Gibbs and a crowd of supporters took two officers from the **Environmental Protection Agency** (EPA) hostage. A group of heavily armed FBI agents occupied the building across the street and gave her seven minutes before they stormed the offices of the Homeowners' Association, where the men were being held. With less than two minutes left in the countdown, Gibbs appeared outside and released the hostages in front of a national television audience. By the middle of the next week, the EPA had announced that the Federal Disaster Assistance Administration would fund immediate evacuation for everyone in the area.

But the families who left the Love Canal area still could not sell their homes, and Gibbs fought to force the federal government to purchase them and underwrite low-interest loans. After she accused President Jimmy Carter of inaction on a national talk show, in the midst of an approaching election, he agreed to purchase the homes. But he refused to meet with her to discuss the loans. Carter signed the appropriations bill in a televised ceremony at the Democratic National Convention in New York City, and Gibbs simply walked onstage in the middle of it and repeated her request for mortgage assistance. The president could do nothing but promise his political support, and the assistance she had been asking for was soon provided.

Gibbs was divorced soon after her family left the Love Canal area. She moved to Washington D.C. with her two children and founded the Citizen's Clearinghouse for Hazardous Wastes in 1981 (later renamed the Center for Health, Environment and Justice in 1997). Its purpose is to assist communities in fighting toxic waste problems, particularly plans for toxic waste dumping sites, and the organization has worked with over 7,000 neighborhood and community groups. Gibbs has also published *Dying from Dioxin, A Citizen's Guide to Reclaiming Our Health and Rebuilding Democracy*. She has appeared on many television and radio shows and has been featured in hundreds of newspaper and magazine articles. Gibbs has also been the subject of several documentaries and television movies. She often speaks at conferences and seminars and has been honored with numerous awards, including the prestigious Goldman Environmental Prize in 1991. Because of Gibbs' activist work, no commercial sites for hazardous wastes have been opened in the United States since 1978.

Gill nets

Gill nets are panels of diamond-shaped mesh netting used for catching fish. When fish attempt to swim through the net their gill covers get caught and they cannot back out. Depending on the **target species**, different mesh sizes are available for use. The top line of the net has a series of floats attached for buoyancy, and the bottom line has **lead** weights to hold the net vertically in the water column.

Gill nets have been in use for many years. They became popular in commercial fisheries in the nineteenth century, evolving from cotton twine netting to the more modern nylon twine netting and monofilament nylon netting. As with many other aspects of **commercial fishing**, the use of gill nets has developed from minor utilization to a major environmental issue. Coupled with **overfishing**, the use of gill nets has caused serious concern throughout the world.

Because gill nets are so efficient at catching fish, they are just as efficient at catching many non-target **species**, including other fishes, **sea turtles**, sea mammals, and sea birds. Gill nets have been used extensively in the commercial fishery for **salmon** and capelin (*Mallotus villosus*). **Dolphins**, **seals**, and sea otters (*Enhydra lutris*) get tangled in the nets, as do diving sea birds such as murres, guillemots, auklets, and puffins that rely on capelin as a mainstay in their diet. Sea turtles are also entangled and drown.

The problem has gotten worse over the last decade with the introduction and extensive use, primarily by foreign fishing fleets, of drift nets. Described as "the most indiscriminate killing device used at sea," drift nets are monofilament gill nets up to 40 mi (64 km) in length. Left at sea for several days and then hauled on board a fishing vessel, these drift nets contain vast numbers of dead marine life, besides the target species, that are simply discarded over the side of the boat. The outrage expressed regarding these "curtains of death" led to a United Nations resolution banning their use in commercial fisheries after the end of 1992. Commercial fishermen who use other types of nets for catching fish, such as the purse seines used in the tuna fishing industry and the bag trawls used in the shrimping industry, have modified their nets and fishing techniques to attempt to eliminate the killing of dolphins and sea turtles, respectively. Unfortunately, such modifications of gill nets are nearly impossible due to the nets' design and the way these nets are used. *See also* Turtle excluder device

Glaciation

The covering of the earth's surface with glacial ice. The term also includes the alteration of the surface of the earth by glacial **erosion** or deposition. Due to the passage of time, ice erosion can be almost unidentifiable; the **weathering** of hard rock surfaces often eliminates minor scratches and other evidence of such glacial activities as the carving of deep valleys. The evidence of deposition, known as depositional imprints, can vary. It may consist of specialized features a few meters above the surrounding terrain, or it may consist

of ground materials several meters in thickness covering wide areas of the landscape.

Only 10% of the earth's surface is currently covered with glacial ice, but it is estimated that 30% had been covered with glacial ice at some time. During the last major glacial period, most of Europe and more than half of the North American continent were covered with ice. The glacial ice of modern day is much thinner than it was in the **ice age**, and the majority of it (85%) is found in **Antarctica**. About 11% of the remaining glacial ice is in Greenland, and the rest is scattered in high altitudes throughout the world.

Moisture and cold temperatures are the two main factors for the formation of glacial ice. Glacial ice in Antarctica is the result of relatively small quantities of snow deposition and low loss of ice because of the cold **climate**. In the middle and low latitudes where the loss of ice, known as ablation, is higher, snowfall tends to be much higher and the glaciers are able overcome ablation by generating large amounts of ice. These types of systems tend to be more active than the glaciers in Antarctica, and the most active of these are often located at high altitudes and in the path of prevailing winds carrying marine moisture.

The **topography** of the earth has been shaped by glaciation. Hills have been reduced in height and valleys created or filled in the movement of glacial ice. *Moraine* is a French term used to describe the ridges and earthen dikes formed near the edges of regional glaciers. Ground moraine is material that accumulates beneath a glacier and has low-relief characteristics, and end moraine is material that builds up along the extremities of a glacier in a ridge-like appearance.

In England, early researchers found stones that were not common to the local ground rock and decided they must have "drifted" there, carried by icebergs on water. Though geology has changed since that time, the term remains and all deposits made by glacial ice are usually identified as drift. These glacial deposits, also known as till, are highly varied in composition. They can be a fine grained deposit, or very coarse with rather large stones present, or a combination of both.

Rock and other soil-like debris are often crushed and ground into very small particles, and they are commonly found as **sediment** in waters flowing from a glacial mass. This material is called glacial flour, and it is carried downstream to form another kind of glacial deposit. During certain cold, dry periods of the year winds can pick up portions of this deposit and scatter it for miles. Many of the different soils in the American "Corn Belt" originated in this way, and they have become some of the more important agricultural soils in the world.

Henry A. Gleason (1882 – 1975)

American ecologist

Henry A. Gleason was a half generation after that small group of midwesterners who founded **ecology** as a discipline in the United States. He was a student of **Stephen Forbes** and his early work in ecology was influenced strongly by Cowles and **Frederic E. Clements**. He did later, however, in 1935, claim standing—bowing only to Cowles and Clements and for some reason not including Forbes—as "the only other original ecologist in the country." And he was original. His work built on that of the founders, but he quickly and actively questioned their ideas and concepts, especially those of Clements, in the process creating controversy and polarization in the ecological community. Gleason called himself an "ecological outlaw" and probably over-emphasized his early lack of acceptance in ecology, but in a resolution of respect from the Ecological Society of America after his death, he was described as a revolutionary and a heretic for his skepticism toward 'established' ideas in ecology. Stanley Cain said that Gleason was never "impressed nor fooled by the philosophical creations of other ecologists, for he has always tested their ideas concerning the association, **succession**, the climax, environmental controls, and **biogeography** against what he knew in **nature**." Gleason was a critical rather than negative thinker and never fully rejected the utility of the idea of community, but the early marginalization of his ideas by mainstream ecologists, and the controversy they created, may have played a role in his later concentration on taxonomy over ecology.

He claimed that if plant associations did exist, they were individualistic and different from area to area, even where most of the same species were present. Gleason did clearly reject, however, Clements' idea of a monoclimax, proclaiming that "the Clementsian concept of succession, as an irreversible trend leading to the climax, was untenable." His field observations also led him to repudiate Clements' organismic concept of the plant community, asking "are we not justified in coming to the general conclusion, far removed from the prevailing opinion, that an association is not an organism?" He went on to say that it is "scarcely even a vegetation unit." He also pointed out the errors in 'Raunkiaer's Law,' on frequency distribution, which as Robert McIntosh noted, was "widely interpreted [in early ecology] as being a fundamental community characteristic indicating homogeneity," and questioned Jaccard's comparison of two communities through a coefficient of similarity that Gleason

believed unduly gave as much weight to rare as to common species.

Gleason's own approach to the study of vegetation emerged from his skills as a floristic botanist, an approach rejected as "old botany" by the founders of ecology. As Nicolson suggests, "a floristic approach entailed giving primacy to the study of the individual plants and their species. This was the essence of [Gleason's] individualistic concept." In hindsight, somewhat ironically then, Gleason used old botany to create a new alternative to what had quickly become dogma in ecology, the centrality of the idea that units of vegetation were real, that the plant association was indispensable to an ecological approach.

Clements was more accepted in the early part of the twentieth century than Gleason, though many ecologists at the time considered both too extreme, just in opposite ways. Today, Clements' theories remain out of favor and some of Gleason's have been revived, though not all of them. Contrary to his own observations, he was persuaded that plants are distributed randomly, at least over small areas, which is seldom if ever the case, though he later backed away from this assertion. He could not accept the theory of continental drift, stating that "the theory requires a shifting of the location of the poles in a way which does considerable violence to botanical and geological facts," and therefore should have few adherents among botanists.

Despite Gleason's skepticism about some of Clements' major ideas, the older botanist was a major influence, especially early in Gleason's career. Especially influential was Clements' rudimentary development of the quadrat method of sampling vegetation, which shaped Gleason's approach to field work; Gleason took the method much further than Clements, and though not trained in mathematics, was the first ecologist to employ a number of quantitative approaches and methods. As McIntosh demonstrated, Gleason, following Forbes lead in aquatic ecology "was clearly one of the earliest and most insightful proponents of the use of quantitative methods in terrestrial ecology."

Gleason was born in the heart of the area where ecology first flourished in the United States. His interest in vegetation and his contributions to ecology were both stimulated by growing up in and doing research on the dynamics of the prairie-forest border. He won bachelor's and master's degrees from the University of Illinois and a Ph.D. from Columbia University. He returned to the University of Illinois as an instructor in botany (1901–1910), where he worked with Stephen Forbes at one of the major American centers of ecological research at the time. In 1910, he moved to the University of Michigan (1910) and while in Ann Arbor, married Eleanor Mattei. Then, in 1919, he moved to the New York Botanical Garden, where he spent the rest of his career, sometimes (reluctantly) as an administrator, always as a research taxonomist. He retired from the Garden in 1951.

Moving out of the Midwest, Gleason also moved out of ecology. Most of his work at the Botanic Garden was taxonomic. He did some ecological work, such as a three-month ecological survey of Puerto Rico in 1926, and a restatement of his "individualistic concept of the plant association, (also in 1926 and also in the *Bulletin of the Torrey Botanical Club*), in which he posed what Nicolson described as "a radical challenge" to the basis of contemporary ecological practice. Gleason's challenge to his colleagues and critics in ecology was to "demolish our whole system of arrangement and classification and start anew with better hope of success." His reasoning was that ecologists had "attempted to arrange all our facts in accordance with older ideas, and have come as a result into a tangle of conflicting ideas and theories." He anticipated twenty-first century thinking that identification on the ground of community and ecosystem as ecological units is arbitrary, noting that vegetation was too continuously varied to identify recurrent associations. He claimed, for example, that "no ecologist would refer the alluvial forests of the upper and lower Mississippi to the same association, yet there is no place along their whole range where one can logically mark a boundary between them. As Mcintosh suggests, "one of Gleason's major contributions to ecology was that he strove to keep the conceptual mold from hardening prematurely."

In his work as a taxonomist for the Garden, Gleason traveled as a plant collector, becoming what he described as "hooked" on tropical American botany, specializing in the large family of melastomes, tropical plants ranging from black mouth fruits to handsome cultivated flowers, a group which engaged him for the rest of his career. His field work, on this family but especially many others, was reinforced by extensive study and identification on material collected by others and made available to him at the Garden.

A major assignment during his New York years, emblematic of his work as a taxonomist, was a revision of the Britton and Brown *Illustrated Flora of the Northeastern United States* (1952) which Maguire describes as a "heavy duty [that] intervened and essentially brought to a close Gleason's excellent studies of the South American floras and [his] detailed inquiry into the Melastomataceae...this great work...occupied some ten years of concentrated, self-disciplined attention." He did publish a few brief pieces on the melastomes after the Britton and Brown, and also two books with Arthur Cronquist, *Manual of Vascular Plants of Northeastern United States and Adjacent Canada* (1963) and the more general *The Natural Geographyof Plants* (1964). The latter, though co-authored, was an overt attempt by Gleason to summarize a life's work and make it accessible to a wider public.

Gleason's early ecological work on species-area relations, the problem of rare species, and his extensive taxonomic work all laid an initial base for contemporary concern among biologists (especially) about the threat to the earth's bio-diversity. Gleason wrote that analysis of "the various species in a single association would certainly show that their optimum environments are not precisely identical," a foreshadowing of later work on niche separation.

McIntosh claimed in 1975 that Gleason's individualistic concept "must be seen not simply as one of historical interest but very likely as one of the key concepts of modern and, perhaps, future ecological thought." A revival of Gleason's emphasis on the individual at mid-twentieth century became one of the foundations for what some scientists in the second half of the twentieth century called a "new ecology," one that rejects imposed order and system and emphasizes the chaos, the randomness, the uncertainty and the unpredictability of natural systems. A call for 'adaptive' resource and environmental management policies flexible enough to respond to unpredictable change in individually variant natural systems is one outgrowth of such changes in thinking in ecology and the **environmental sciences**.

Glen Canyon Dam

Until 1963, Glen Canyon was one of the most beautiful stretches of natural scenery in the American West. The canyon had been cut over thousands of years as the **Colorado River** flowed over sandstone that once formed the floor of an ancient sea. The colorful walls of Glen Canyon were often compared to those of the Grand Canyon, only about 50 mi (80 km) downstream.

Humans have long seen more than beauty in the canyon, however. They have envisioned the potential value of a water **reservoir** that could be created by damming the Colorado. In a region where water can be as valuable as gold, plans for the construction of a giant **irrigation** project with water from a Glen Canyon dam go back to at least 1850.

Flood control was a second argument for the construction of such a dam. Like most western rivers, the Colorado is wild and unpredictable. When fed by melting snows and rain in the spring, its natural flow can exceed 300,000 ft^4 (8,400 m^4) per second. At the end of a hot dry summer, flow can fall to less than 1% of that value. The river's water temperature can also fluctuate widely, by more than 36°F (20°C) in a year. A dam in Glen Canyon held the promise of moderating this variability.

By the early 1900s, yet a third argument for building the dam was proposed—the generation of hydroelectric power. Both the technology and the demand were reaching the point that power generated at the dam could be supplied to Phoenix, Los Angeles, San Diego, and other growing urban areas in the Far West.

Some objections were raised in the 1950s when construction of a Glen Canyon Dam was proposed, and environmentalists fought to protect this unique natural area. The 1950s and early 1960s were not, however, an era of high environmental sensitivity, and plans for the dam eventually were approved by the U. S. Congress. Construction of the dam, just south of the Utah-Arizona border, was completed in 1963 and the new lake it created, Lake Powell, began to develop. Seventeen years later, the lake was full holding a maximum of 27 million acre-feet of water.

The environmental changes brought about by the dam are remarkable. The river itself has changed from a muddy brown color to a clear crystal blue as the sediments it carries are deposited behind the dam in Lake Powell. **Erosion** of river banks downstream from the dam has lessened considerably as spring floods are brought under control. Natural beaches and sandbars, once built up by deposited **sediment**, are washed away. River temperatures have stabilized at an annual average of about 50°F (10°C). These physical changes have brought about changes in **flora** and **fauna** also. Four **species** of fish native to the Colorado have become extinct, but at least 10 species of birds are now thriving where they barely survived before. The **biotic community** below the dam is significantly different from what it was before construction.

During the 1980s, questions about the dam's operation began to grow. A number of observers were especially concerned about the fluctuations in flow through the dam, a pattern determined by electrical needs in distant cities. During peak periods of electrical demand, operators increase the flow of water though the dam to a maximum of 30,000 ft^4

(840 m^4) per second. At periods of low demand, that flow may be reduced to 1,000 ft^4 (28 m^4) per second. As a result of these variations, the river below the dam can change by as much as 13 ft (4 m) in height in a single 24-hour period. This variation can severely damage riverbanks and can have unsettling effects on **wildlife** in the area as, for example, fish are stranded on the shore or swept away from spawning grounds. River-rafting is also severely affected by changing river levels as rafters can never be sure from day to day what water conditions they may encounter.

Operation of the Glen Canyon Dam is made more complex by the fact that control is divided up among at least three different agencies in the U. S. Department of the Interior, the **Bureau of Reclamation**, the **Fish and Wildlife Service**, and the **National Park Service**, all with somewhat different missions. In 1982, a comprehensive re-analysis of the Glen Canyon area was initiated. A series of environmental studies called the Glen Canyon Environmental Studies were designed and carried out over much of the following decade. In addition, Interior Secretary Manuel Lujan announced in 1989 that an **environmental impact statement** on the downstream effects of the dam would be conducted.

The purpose of the environmental impact statement was to find out if other options were available for operating the dam that would minimize harmful effects on the **environment**, recreational opportunities, and Native American activities while still allowing the dam to produce sufficient levels of hydroelectric power. The effects studied included water, sediment, fish, vegetation, wildlife and **habitat**, endangered and other special-status species, cultural resources, **air quality**, **recreation**, hydropower, and non-use value (i.e., general appreciation of **natural resources**).

Nine different operating options for the dam were considered. These options fell into three general categories: unrestricted fluctuating flows (two alternative modes); restricted fluctuating flows (four modes); and steady flows (three modes).

The final choice made was one that involves "periodic high, steady releases of short duration" that reduce the dam's performance significantly below its previous operating level. The criterion for this decision was the protection and enhancement of downstream resources while continuing to permit a certain level of flexibility in the dam's operation.

A later series of experiments was designed to see what could be done to restore certain downstream resources that have been destroyed or damaged by the dam's operation. Between March 26 and April 2, 1996, the U.S. Bureau of **Reclamation** released unusually large amounts of water from the dam. The intent was to reproduce the large scale **flooding** on the Colorado River that had normally occurred every spring before the dam was built.

The primary focus of this project was to see if downstream sandbars could be restored by the flooding. The sandbars have traditionally been used as campsites and have been a major mechanism for the removal of **silt** from backwater channels used by native fish. Depending on the final results of this study, the Bureau will determine what changes, if any, should be taken in adjusting flow patterns over the dam to provide for maximum environmental benefit downstream along with power output. *See also* Alternative energy sources; Riparian land; Wild river

Global Environment Monitoring System

A data-gathering project administered by the **United Nations Environment Programme**. The Global Environment Monitoring System (GEMS) is one aspect of the modern understanding that environmental problems ranging from the **greenhouse effect** and **ozone layer depletion** to the preservation of **biodiversity** are international in scope. The system was inaugurated in 1975, and it monitors weather and **climate** changes around the world, as well as variations in soils, the health of plant and animal **species**, and the environmental impact of human activities.

GEMS was not intended to replace any existing systems; it was designed to coordinate the collection of data on the environment, encouraging other systems to supply information it believed was being omitted. In addition to coordinating the gathering of this information, the system also publishes it in an uniform and accessible fashion, where it can be used and evaluated by environmentalists and policy makers.

GEMS operates 25 information networks in over 142 countries. These networks monitor **air pollution**, including the release of **greenhouse gases** and changes in the **ozone** layer, and **air quality** in various urban center; they also gather information on **water quality** and food contamination in cooperation with the World Health Organization and the Food and Agriculture Organization of the United Nations.

Global Forum

The Global Forum of Spiritual and Parliamentary Leaders on Human Survival is a worldwide organization of scientists, leaders of world religions, and parliamentarians who are attempting to change environmental and developmental values in their countries. Members include local, national, and international leaders in the arts, business, community action, education, faith, government, media, and youth sectors.

Historically, lawmakers and spiritual leaders have differed in their views toward stewardship of the earth. A conference held in Oxford, England, in 1988, and attended by 200 spiritual and legislative leaders brought these groups together with scientists to discuss solutions to worldwide environmental problems. Speakers included the Dalai Lama, Mother Teresa, and the Archbishop of Canterbury, who conferred with experts such as Carl Sagan, Kenyan environmentalist Wangari Maathai, and **Gaia hypothesis** scientist James Lovelock. As a result of the Oxford conference, the Soviet Union invited the Global Forum to convene an international meeting on critical survival issues. The Moscow conference, called the Global Forum on Environment and Development, took place in January 1990. Over 1,000 spiritual and parliamentary leaders, scientists, artists, journalists, businessmen, and young people from eighty-three countries attended the Moscow Forum. One initiative of the Moscow Forum was a joint commitment by scientists and religious leaders to preserve and cherish the earth.

The Global Forum tries not to duplicate the activities of other environmental groups but works to relate global issues to local environments. For example, participants at the first U.S.-based Global Forum conference in Atlanta in May 1992, learned about the local effects of global problems such as **tropical rain forest** destruction, global warming, and **waste management**. The Global Forum has initiated seminars worldwide on ethical implications of the environmental crisis. Artists learn about the role of the arts in communicating global survival issues. Business leaders promote **sustainable development** at the highest levels of business and industry. Young people petition their schools to include curriculum on environmental issues as required subjects.

Global Releaf

Global Releaf, an international citizen action and education program, was initiated in 1988 by the 115-year-old American Forestry Association in response to the worldwide concern over global warming and the **greenhouse effect**. Campaigning under the slogan "Plant a tree, cool the globe," its over 112,000 members began the effort to reforest the earth one tree at a time.

In 1990, Global Releaf began Global Releaf Forest, an effort to restore damaged **habitat** on public lands through tree plantings Global Releaf Fund is its urban counterpart. Using each one-dollar donation to plant one tree resulted in the planting of more than four million trees on 70 sites in 33 states. By involving local citizens and resource experts in each project, the program ensures that the right **species** are planted in the right place at the right time. Results include the protection of endangered and threatened animals, restoration of native species, and improvement of recreational opportunities.

Funding for the program has come largely from government agencies, corporations, and non-profit organizations. Chevrolet-Geo celebrated the planting of its millionth tree in October 1996. The Texaco/Global Releaf Urban Tree Initiative, utilizing more than 6,000 Texaco volunteers, has helped local groups plant more than 18,000 large trees and invested over $2.5 million in projects in twelve cities. Outfitter Eddie Bauer began an "Add a Dollar, Plant a Tree" program to fund eight Global Releaf Forest sites in the United States and Canada, planting close to 350,000 trees.

The Global Releaf Fund also helps finance urban and rural reforestation on foreign **soil** in projects undertaken with its international partners. Engine manufacturer, Briggs & Stratton, for example, has made possible tree plantings both in the United States and in Ecuador, England, Germany, Poland, Romania, Slovakia, South Africa, and Ukraine, while Costa Rica, Gambia, and the Philippines have benefitted from picture-frame manufacturer Larsen-Juhl.

Unfortunately, not enough funding exists to grant all the requests; in 1996, only 40% of the proposed projects received financial backing. Forced to pick and choose, the review board favors those projects which aim to protect endangered and threatened species. Burned forests and natural disaster areas—like the Francis Marion **National Forest** in South Carolina, devastated by 1989's **Hurricane** Hugo—are also high on the priority list, as are streamside woodlands and landfills.

Looking to the future, Global Releaf 2000 was launched in 1996 with the aim of encouraging the planting of 20 million trees, increasing the canopy in select cities by 20%, and expanding the program to include private lands and sanitary landfills. A 20-city survey done in 1985 by

American Forests showed that four trees die for every one planted in United States cities and that the average city tree lives only 32 years (just seven years, downtown). With these facts in mind, Global Releaf asks that communities plant twice as many trees as are lost in the next decade. In August of 2001, more than 19 million trees had been planted.

Goiter

Generally refers to any abnormal enlargement of the thyroid gland. The most common type of goiter, the simple goiter, is caused by a deficiency of iodine in the diet. In an attempt to compensate for this deficiency, the thyroid gland enlarges and may become the size of a large softball in the neck. The general availability of table salt to which potassium iodide has been added ("iodized" salt) has greatly reduced the incidence of simple goiter in many parts of the world. A more serious form of goiter, toxic goiter, is associated with hyperthyroidism. The etiology of this condition is not well understood. A third form of goiter occurs primarily in women and is believed to be caused by changes in hormone production.

Golf courses

The game of golf appears to be derived from ancient stick-and-ball games long played in western Europe. However, the first documented rules of golf were established in 1744, in Edinburgh, Scotland. Golf was first played in the United States in the 1770s, in Charleston, South Carolina. It was not until the 1880s, however, that the game began to become widely popular, and it has increasingly flourished since then. In 2002, there were about 16,000 golf courses in the United States, and thousands more in much of the rest of the world.

Golf is an excellent form of outdoor **recreation**. There are many health benefits of the game, associated with the relatively mild form of exercise and extensive walking that can be involved. However, the development and management of golf courses also results in environmental damage of various kinds. The damage associated with golf courses can engender intense local controversy, both for existing facilities and when new ones are proposed for development.

The most obvious environmental affect of golf courses is associated with the large amounts of land that they appropriate from other uses. Depending on its design, a typical 18-hole golf course may occupy an area of about 100-200 acres. If the previous use of the land was agricultural, then conversion to a golf course results in a loss of food production. Alternatively, if the land previously supported forest or some other kind of natural **ecosystem**, then the conversion results in a large, direct loss of **habitat** for native **species** of plants and animals.

In fact, some particular golf courses have been extremely controversial because their development caused the destruction of the habitat of **endangered species** or rare kinds of natural ecosystems. For instance, the Pebble Beach Golf Links course, one of the most famous in the world, was developed in 1919 on the Monterey Peninsula of central California, in natural coastal and forest habitats that harbor numerous rare and endangered species of plants and animals. Several additional gold courses and associated tourist facilities were subsequently developed nearby, all of them also displacing natural ecosystems and destroying the habitat of **rare species**. Most of those recreational facilities were developed at a time when not much attention was paid to the needs of endangered species. Today, however, the **conservation** of **biodiversity** is considered an important issue. It is quite likely that if similar developments were now proposed in such critical habitats, citizen groups would mount intense protests and government regulators would not allow the golf courses to be built.

The most intensively modified areas on golf courses are the fairways, putting greens, aesthetic lawns and gardens, and other highly managed areas. Because these kinds of areas are intrinsic to the design of golf courses, a certain amount of loss of natural habitat is inevitable. To some degree, however, the net amount of habitat loss can be decreased by attempting, to the degree possible, to retain natural community types within the golf course. This can

be done particularly effectively in the brushy and forested areas between the holes and their approaches. The habitat quality in these less-intensively managed areas can also be enhanced by providing nesting boxes and brush piles for use by birds and small mammals, and by other management practices known to favor **wildlife**. Habitat quality is also improved by planting native species of plants wherever it is feasible to do so.

In addition to land appropriation, some of the management practices used on golf courses carry the risk of causing local environmental damage. This is particularly the case of putting greens, which are intensively managed to maintain an extremely even and consistent lawn surface.

For example, to maintain a **monoculture** of desired species of grasses on putting greens and lawns, intensive management practices must be used. These include frequent mowing, **fertilizer** application, and the use of a variety of pesticidal **chemicals** to deal with various pests affecting the turfgrass. This may involve the application of such herbicides as Roundup (glyphosate), **2,4-D**, MCPP, or Dicamba to deal with undesirable weeds. **Herbicide** application is particularly necessary when putting greens and lawns are being first established. Afterward their use can be greatly reduced by only using spot-applications directly onto turf-grass weeds. Similarly, fungicides might be used to combat infestations of turf-grass disease **fungi**, such as the fusarium blight (*Fusarium culmorum*), take-all patch (*Gaeumannomyces graminis*), and rhizoctonia blight (*Rhizoctonia solani*).

Infestations by turf-damaging insects may also be a problem, which may be dealt with by one or more insecticide applications. Some important insect pests of golf-course turf-grasses include the Japanese beetle (*Popillia japonica*), chafer beetles (*Cyclocephala* spp.), June beetles (*Phyllophaga* spp.), and armyworm beetle (*Pseudaletia unipuncta*). Similarly, rodenticides may be needed to get rid of moles (*Scalopus aquaticus*) and their burrows.

Golf courses can also be a major user of water, mostly for the purposes of **irrigation** in dry climates or during droughty periods. This can be an important problem in semi-arid regions, such as much of the southwestern U.S., where water is a scare and valuable commodity with many competing users. To some degree, water use can be decreased by ensuring that irrigation is only practiced when necessary, and only in specific places where it is needed, rather than according to a fixed schedule and in a broadcast manner. In some climatic areas, nature-scaping and other low-maintenance practices can be used over extensive areas of golf courses. This can result in intensive irrigation only being practiced in key areas, such as putting greens, and to a lesser degree fairways and horticultural lawns.

Many golf courses have ponds and lakes embedded in their spatial design. If not carefully managed, these waterbodies can become severely polluted by nutrients, pesticides, and eroded materials. However, if care is taken with golf-course management practices, their ponds and lakes can sustain healthy ecosystems and provide refuge habitat for local native plants and animals.

Increasingly, golf-course managers and industry associations are attempting to find ways to support their sport while not causing an unacceptable amount of environmental damage. One of the most important initiatives of this kind is the Audubon Cooperative Sanctuary Program for Golf Courses, run by the Audubon International, a private conservation organization. Since 1991, this program has been providing **environmental education** and conservation advice to golf-course managers and designers. By 2002, membership in this Audubon program had grown to more than 2,300 courses in North America and elsewhere in the world.

The Audubon Cooperative Sanctuary Program for Golf Courses provides advice to help planners and managers with: (a) environmental planning; (b) wildlife and habitat management; (c) chemical use reduction and safety; (d) **water conservation**; and (e) outreach and education about environmentally appropriate management practices. If a golf course completes recommended projects in all of the components of the program, it receives recognition as a Certified Audubon Cooperative Sanctuary. This allows the golf course to claim that it is conducting its affairs in a certifiably "green" manner. This results in tangible environmental benefits of various kinds, while being a source of pride of accomplishment for employees and managers, and providing a potential marketing benefit to a clientele of well-informed consumers.

There are many specific examples of environmental benefits that have resulted from golf courses engaged in the Audubon Cooperative Sanctuary Program. For instance, seven golf courses in Arizona and Washington have allowed the installation of 150 artificial nesting burrows for burrowing owls (*Athene cunicularia*), an endangered species, on suitable habitat on their land. In 2000, Audubon International conducted a survey of cooperating golf courses, and the results were rather impressive. About 78% of the respondents reported that they had decreased the total amount of turf-grass area on their property; 73% had taken steps to increase the amount of wildlife habitat; 45% were engaged in an ecosystem restoration project; 90% were attempting to use native plants in their horticulture; and 85% had decreased their use of pesticides and 91% had switched to lower-toxicity chemicals. Just as important, about half of the respondents believed that there had been an improvement in the playing quality of their golf course and in the satisfaction of both employees and their client golfers. Moreover, none of the respondents believed that any of these values had been degraded as a result of adopting the management practices advised by the Audubon International program.

These are all highly positive indicators. They suggest that the growing and extremely popular sport of golf can, within limits, potentially be practiced in ways that do not cause unacceptable levels of environmental and ecological damage.

Good wood

Good wood, or smart wood, is a term certifying that the wood is harvested from a forest operating under environmentally sound and sustainable practices. A "certified wood" label indicates to consumers that the wood they purchase comes from a forest operating within specific guidelines designed to ensure future use of the forest. A well-managed forestry operation takes into account the overall health of the forest and its ecosystems, the use of the forest by indigenous people and cultures, and the economic influences the forest has on local communities. Certification of wood allows the wood to be traced from harvest through processing to the final product (i.e., raw wood or an item made from wood) in an attempt to reduce uncontrollable **deforestation**, while meeting the demand for wood and wood products by consumers around the world.

Public concern regarding the disappearance of tropical forests initially spurred efforts to reduce the destruction of vast acres of rainforests by identifying environmentally responsible forestry operations and encouraging such practices by paying foresters higher prices. Certification, however, is not limited to tropical forests. All forest types—tropical, temperate, and boreal (those located in northern climes)—from all countries may apply for certification. Plantations (stands of timber that have been planted for the purpose of **logging** or that have been altered so that they no longer support the ecosystems of a natural forest) may also apply for certification.

Certification of forests and forest owners and managers is not required. Rather, the process is entirely voluntary. Several organizations currently assess forests and **forest management** operations to determine whether they meet the established guidelines of a well-managed, sustainable forest. The Forest Stewardship Council (FSC), founded in 1993, is an organization of international members with environmental, forestry, and socioeconomic backgrounds that monitors these organizations and verifies that the certification they issue is legitimate.

A set of 10 guiding principles known as Principles and Criteria (P&C) were established by the FSC for certifying organizations to utilize when evaluating forest management operations. The P&C address a wide range of issues, including compliance with local, national, and international laws and treaties; review of the forest operation's management plans; the religious or cultural significance of the forest to the indigenous inhabitants; maintenance of the rights of the indigenous people to use the land; provision of jobs for nearby communities; the presence of threatened or **endangered species**; control of excessive **erosion** when building roads into the forest; reduction of the potential for lost **soil** fertility as a result of harvesting; protection against the invasion of non-native **species**; **pest** management that limits the use of certain chemical types and of genetically altered organisms; and protection of forests when deemed necessary (for example, a forest that protects a **watershed** or that contains threatened and/or endangered species).

Guarding against illegal harvesting is a major hurdle for those forest managers working to operate within the established regulations for certification. Forest devastation occurs not only from harvesting timber for wood sales but when forests are clear cut to make way for cattle crazing or farming, or to provide a fuel source for local inhabitants. Illegal harvesting often occurs in developing countries where enforcement against such activities is limited (for example, the majority of the trees harvested in Indonesia are done so illegally).

Critics argue against the worthiness of managing forests, suggesting that the logging of select trees from a forest should be allowed and that once completed, the remaining forest should be placed off limits to future logging. Nevertheless, certified wood products are in the market place; large wood and wood product suppliers are offering certified wood and wood products to their consumers. In 2001 the Forest Leadership Forum (a group of environmentalists, forest industry representatives, and retailers) met to identify how wood retailers can promote sustainable forests. It is hoped that consumer demand for good wood will drive up the number of forests participating in the certification program,

thereby reducing the rate of irresponsible deforestation of the world's forests.

Jane Goodall (1934 –)

English primatologist and ethnologist

Jane Goodall is known worldwide for her studies of the **chimpanzees** of the Gombe Stream Reserve in Tanzania, Africa. She is well respected within the scientific community for her ground-breaking field studies and is credited with the first recorded observation of chimps eating meat and using and making tools. Because of Goodall's discoveries, scientists have been forced to redefine the characteristics once considered as solely human traits. Goodall is now leading efforts to ensure that animals are treated humanely both in their wild habitats and in captivity.

Goodall was born in London, England, on April 3, 1934, to Mortimer Herbert Goodall, a businessperson and motor-racing enthusiast, and the former Margaret Myfanwe Joseph, who wrote novels under the name Vanne Morris Goodall. Along with her sister, Judy, Goodall was reared in London and Bournemouth, England. Her fascination with animal behavior began in early childhood. In her leisure time, she observed native birds and animals, making extensive notes and sketches, and read widely in the literature of zoology and ethnology. From an early age, she dreamed of traveling to Africa to observe exotic animals in their natural habitats.

Goodall attended the Uplands private school, receiving her school certificate in 1950 and a higher certificate in 1952. At age eighteen she left school and found employment as a secretary at Oxford University. In her spare time, she worked at a London-based documentary film company to finance a long-anticipated trip to Africa. At the invitation of a childhood friend, she visited South Kinangop, Kenya. Through other friends, she soon met the famed anthropologist Louis Leakey, then curator of the Coryndon Museum in Nairobi. Leakey hired her as a secretary and invited her to participate in an anthropological dig at the now famous Olduvai Gorge, a site rich in fossilized prehistoric remains of early ancestors of humans. In addition, Goodall was sent to study the vervet monkey, which lives on an island in Lake Victoria.

Leakey believed that a long-term study of the behavior of higher primates would yield important evolutionary information. He had a particular interest in the chimpanzee, the second most intelligent primate. Few studies of chimpanzees had been successful; either the size of the safari frightened the chimps, producing unnatural behaviors, or the observers spent too little time in the field to gain comprehensive knowledge. Leakey believed that Goodall had the proper temperament to endure long-term isolation in the wild. At his prompting, she agreed to attempt such a study. Many experts objected to Leakey's selection of Goodall because she had no formal scientific education and lacked even a general college degree.

While Leakey searched for financial support for the proposed Gombe Reserve project, Goodall returned to England to work on an animal documentary for Granada Television. On July 16, 1960, accompanied by her mother and an African cook, she returned to Africa and established a camp on the shore of Lake Tanganyika in the Gombe Stream Reserve. Her first attempts to observe closely a group of chimpanzees failed; she could get no nearer than 500 yd (457 m) before the chimps fled. After finding another suitable group of chimpanzees to follow, she established a nonthreatening pattern of observation, appearing at the same time every morning on the high ground near a feeding area along the Kakaombe Stream valley. The chimpanzees soon tolerated her presence and, within a year, allowed her to move as close as 30 ft (9 m) to their feeding area. After two years of seeing her every day, they showed no fear and often came to her in search of bananas.

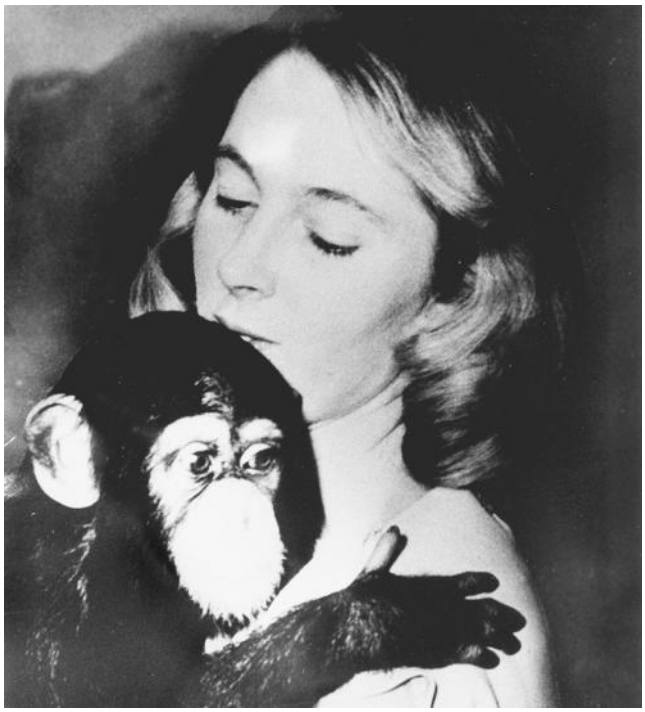
Goodall used her newfound acceptance to establish what she termed the "banana club," a daily systematic feeding method she used to gain trust and to obtain a more thorough understanding of everyday chimpanzee behavior. Using this method, she became closely acquainted with more than half of the reserve's one hundred or more chimpanzees. She imitated their behaviors, spent time in the trees, and ate their foods. By remaining in almost constant contact with the chimps, she discovered a number of previously unobserved behaviors. She noted that chimps have a complex social system, complete with ritualized behaviors and primitive but discernible communication methods, including a primitive "language" system containing more than twenty individual sounds. She is credited with making the first recorded observations of chimpanzees eating meat and using and making tools. Tool making was previously thought to be an exclusively human trait, used, until her discovery, to distinguish man from animal. She also noted that chimpanzees throw stones as weapons, use touch and embraces to comfort one another, and develop long-term familial bonds. The male

plays no active role in family life but is part of the group's social **stratification**. The chimpanzee "caste" system places the dominant males at the top. The lower castes often act obsequiously in their presence, trying to ingratiate themselves to avoid possible harm. The male's rank is often related to the intensity of his entrance performance at feedings and other gatherings.

Ethologists had long believed that chimps were exclusively vegetarian. Goodall witnessed chimps stalking, killing, and eating large insects, birds, and some bigger animals, including baby baboons and bushbacks (small antelopes). On one occasion, she recorded acts of cannibalism. In another instance, she observed chimps inserting blades of grass or leaves into termite hills to lure worker or soldier termites onto the blade. Sometimes, in true toolmaker fashion, they modified the grass to achieve a better fit. Then they used the grass as a long-handled spoon to eat the termites.

In 1962 Baron Hugo van Lawick, a Dutch **wildlife** photographer, was sent to Africa by the National Geographic Society to film Goodall at work. The assignment ran longer than anticipated; Goodall and van Lawick were married on March 28, 1964. Their European honeymoon marked one of the rare occasions on which Goodall was absent from Gombe Stream. Her other trips abroad were necessary to fulfill residency requirements at Cambridge University, where she received a Ph.D. in ethnology in 1965, becoming only the eighth person in the university's long history who was allowed to pursue a Ph.D. without first earning a baccalaureate degree. Her doctoral thesis, "Behavior of the Free-Ranging Chimpanzee," detailed her first five years of study at the Gombe Reserve.

Van Lawick's film, *Miss Goodall and the Wild Chimpanzees,* was first broadcast on American television on December 22, 1965. The film introduced the shy, attractive, unimposing yet determined Goodall to a wide audience. Goodall, van Lawick (along with their son, Hugo, born in 1967), and the chimpanzees soon became a staple of American and British public television. Through these programs, Goodall challenged scientists to redefine the long-held "differences" between humans and other primates.



Goodall's fieldwork led to the publication of numerous articles and five major books. She was known and respected first in scientific circles and, through the media, became a minor celebrity. *In the Shadow of Man,* her first major text, appeared in 1971. The book, essentially a field study of chimpanzees, effectively bridged the gap between scientific treatise and popular entertainment. Her vivid prose brought the chimps to life, although her tendency to attribute human behaviors and names to chimpanzees struck some critics being as manipulative. Her writings reveal an animal world of social drama, comedy, and tragedy where distinct and varied personalities interact and sometimes clash.

From 1970 to 1975 Goodall held a visiting professorship in psychiatry at Stanford University. In 1973 she was appointed honorary visiting professor of Zoology at the University of Dar es Salaam in Tanzania, a position she still holds. Her marriage to van Lawick over, she wed Derek Bryceson, a former member of Parliament, in 1973. He has since died. Until recently, Goodall's life has revolved around Gombe Stream. But after attending a 1986 conference in Chicago that focused on the ethical treatment of chimpanzees, she began directing her energies more toward educating the public about the wild chimpanzee's endangered **habitat** and about the unethical treatment of chimpanzees that are used for scientific research.

To preserve the wild chimpanzee's **environment**, Goodall encourages African nations to develop nature-friendly tourism programs, a measure that makes wildlife into a profitable resource. She actively works with business and local governments to promote ecological responsibility. Her efforts on behalf of captive chimpanzees have taken her around the world on a number of lecture tours. She outlined her position strongly in her 1990 book *Through a Window*: "The more we learn of the true nature of non-human animals, especially those with complex brains and corresponding complex social behaviour, the more ethical concerns are raised regarding their use in the service of man-whether this be in entertainment, as 'pets,' for food, in research laboratories or any of the other uses to which we subject them. This concern is sharpened when the usage in question leads to intense physical or mental suffering-as is so often true with regard to vivisection."

Goodall's stance is that scientists must try harder to find alternatives to the use of animals in research. She has openly declared her opposition to militant **animal rights** groups who engage in violent or destructive demonstrations. Extremists on both sides of the issue, she believes, polarize thinking and make constructive dialogue nearly impossible. While she is reluctantly resigned to the continuation of animal research, she feels that young scientists must be educated to treat animals more compassionately. "By and large," she has written, "students are taught that it is ethically acceptable to perpetrate, in the name of science, what, from the point of view of animals, would certainly qualify as torture."

Goodall's efforts to educate people about the ethical treatment of animals extends to young children as well. Her 1989 book, *The Chimpanzee Family Book,* was written specifically for children, to convey a new, more humane view of wildlife. The book received the 1989 Unicef/Unesco Children's Book-of-the-Year award, and Goodall used the prize money to have the text translated into Swahili. It has been distributed throughout Tanzania, Uganda, and Bu-

Jane Goodall. (The Library of Congress.)

rundi to educate children who live in or near areas populated by chimpanzees. A French version has also been distributed in Burundi and Congo.

In recognition of her achievements, Goodall has received numerous honors and awards, including the Gold Medal of **Conservation** from the San Diego Zoological Society in 1974, the J. Paul Getty Wildlife Conservation Prize in 1984, the Schweitzer Medal of the **Animal Welfare Institute** in 1987, the National Geographic Society Centennial Award in 1988, and the Kyoto Prize in Basic Sciences in 1990. In 1995, Goodall was presented with a CBE (Commander of the British Empire) from Queen Elizabeth II. Many of Goodall's endeavors are conducted under the auspices of the Jane Goodall Institute for Wildlife Research, Education, and Conservation, a nonprofit organization located in Ridgefield, Connecticut. In April of 2002, it was revealed that Goodall was chosen to be a United Nations Messenger of Peace.

Albert Gore Jr. (1948 –)

American former U.S. representative, senator and vice president of the United States

Albert Gore, Jr. was born and raised in Washington, D.C., where his father was a well-known and widely respected representative and later senator from Tennessee. Gore attended St. Alban's Episcopal School for Boys, where he excelled both academically and athletically. He later went to Harvard, earning a bachelor's degree in government. After graduation he enlisted in the army, serving as a reporter in Vietnam in a war he was opposed to. After completing his tour of duty, in 1974 Gore entered the law school at Vanderbilt University. Following in his father's footsteps, Gore ran for Congress, was elected, and served five terms before running for and winning a Senate seat in 1984. He served in the Senate until 1992, when then-governor and Democratic presidential candidate Bill Clinton selected him as his vice presidential running-mate. After winning the 1992 election Vice President Gore became the Clinton administration's chief environmental advisor. He was also largely responsible for President Clinton's selection of **Carol Browner** as head of the **Environmental Protection Agency** (EPA) and Bruce Babbit as Secretary of the Interior.

A self-described "raging moderate," Gore for more than two decades championed environmental causes and drafted and sponsored environmental legislation in the Senate. He was one of two U.S. senators to attend and take an active part in the 1992 U.N.-sponsored Rio Summit on the **environment**, and after he became vice president in 1993, he took a leading role in shaping the Clinton administration's environmental agenda. As vice president, Gore's ability to shape that agenda was perhaps somewhat limited. At the close of Clinton's first term, most environmental organizations rated his administration's record on environmental matters as mixed, at best. Yet clearly environmental groups had more access to the White House than they had ever had before. And in his second term, Gore was thought to be responsible for salvaging the 1997 Kyoto agreement on **climate** change when he flew to Japan as negotiations were falling apart and personally represented a new American position.

Gore's most notable contribution to the environmental movement might be as an author. With a wealth of statistical and scientific evidence, Gore's 1992 book *Earth in the Balance* makes the case that careless development and growth have damaged the natural environment; but better policies and regulations will supply incentives for more environmentally responsible actions by individuals and corporations. For example, a so-called **carbon tax** could provide financial incentives for developing new, nonpolluting energy sources such as solar and wind power. Corporations could also be given tax credits for using these new sources. By structuring a system of incentives that favors the protection and restoration of the natural environment, government at the local, national, and (through the United Nations) international levels can restore the balance between satisfying human needs and protecting the earth's environment. But restoring this balance, Gore maintained in his book, requires more than public policy and legislation; it requires changes in basic beliefs and attitudes toward **nature** and all living creatures. More specifically, environmental protection and restoration requires a willingness on the part of individuals to accept responsibility for their actions (or inaction). At the individual level, environmental protection means living, working, eating, and recreating responsibly, with an eye to one's effects on the natural and social environment, now and in the future in which our children and their children will survive.

Despite the strong stances Gore articulated in *Earth in the Balance*, his achievements as vice president under Clinton were more moderate. His former staffer Carol Browner headed the EPA, and she prevailed in promoting several major pieces of environmental legislation. But she had to withstand concerted attacks on her and her office by the Republican majority in the House and Senate after 1994. Gore had managed to save the Kyoto treaty on climate change by his personal efforts in 1997, but the Clinton administration never committed to specific actions to cut carbon-dioxide emissions. In August 1998 Gore met with the leaders of several environmental groups and explained to them that he had no political backing for advocating controversial actions like limiting **pollution** from coal-burning **power plants**. When he ran for president in 2000, the environment was not a strong feature in his campaign, though this was an area where he had sharp differences with his opponent, George W. Bush. In the last months of the campaign, Gore found himself defending his record on the environment against Green Party candidate **Ralph Nader**. Though Gore had the backing of the **Sierra Club** and other major environmental groups, Nader accused Gore of "eight years of principles betrayed and promises broken." In the end Gore lost the election to Bush, who quickly reversed Clinton administration environmental policies such as new standards on drinking water safety, and refused to endorse the Kyoto climate change treaty.

Albert Gore, Jr. (Corbis-Bettmann. Reproduced by permission.)

After losing the election, Gore began lecturing at Fisk University in Nashville, at UCLA, and at the School of Journalism at Columbia University. Out of office, he remained for the most part out of the public eye. But he did speak at Vanderbilt University on **Earth Day** in 2002, roundly criticizing George W. Bush for his **environmental policy**. Gore noted that some of his more extreme environmental stances, such as calling for new technology to replace the internal **combustion** engine, were now being considered even by Republican lawmakers. In mid-2002, Gore would not commit to another run for the presidency. But it did seem that he stood by his earlier ideas, and would continue to identify himself with the environmental movement.

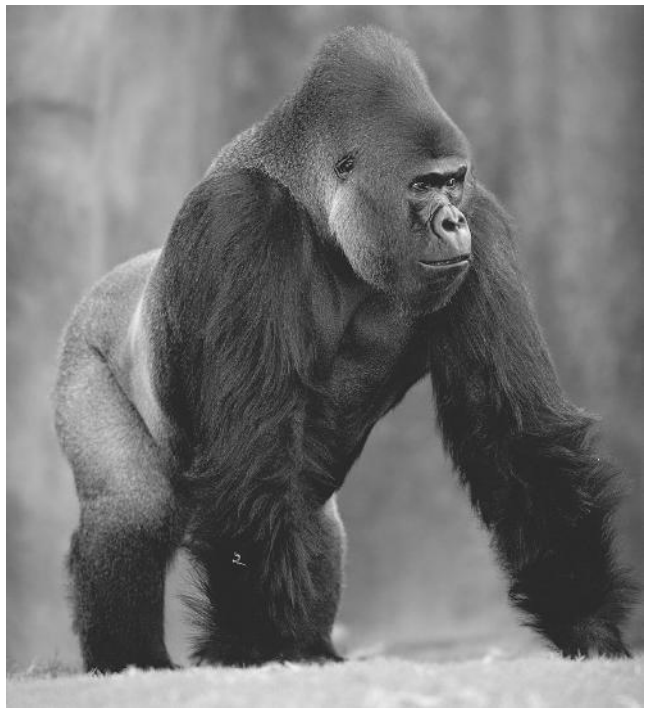
Gorillas



Gorillas (*Gorilla gorilla*) inhabit the forests of Central Africa and are the largest and most powerful of all primates. Adult males stand 6 ft (1.8 m) upright (an unnatural position for a gorilla) and weigh up to 450 lb (200 kg), while females are much smaller. Gorillas live to about 44 years and mature males (those usually over 13 years), or silverbacks, are marked by a band of silver-gray hair on their backs.

Gorillas live in small family groups of several females and their young, led by a dominant silverback male. The females comprise a harem for the silverback, who holds the sole mating rights in the troop. Like humans, female gorillas produce one infant after a gestation period of nine months. The large size and great strength of the silverback are advantages in competing with other males for leadership of the group and in defending the group against outside threats.

During the day these ground-living apes move slowly through the forest, selecting **species** of leaves, fruit, and stems from the surrounding vegetation. Their home range is about 9–14 mi^2 (25–40 km^2). At night the family group sleeps in trees, resting on platform nests that they make from branches; silverbacks usually sleep at the foot of the tree.

Gorillas belong to the family Pongidae (which includes **chimpanzees** *Pan*], orangutans [*Pongo pygmaeus*], and **gibbons** [genus *Hylobates*). Together with chimpanzees, gorillas are the animal species most closely related to man. Like most megavertebrates, gorilla numbers are declining rapidly and only about 40,000 remain in the wild. There are three subspecies, the western lowland gorilla (*G. g. gorilla*), the eastern lowland gorilla (*G. g. graueri*), and the mountain gorilla (*G. g. beringei*). The rusty-gray western lowland gorillas are found in Nigeria, Cameroon, Equatorial Guinea, Gabon, Congo, Angola, Central African Republic, and Zaire (now Democratic Republic of the Congo [DRC]). The black-haired eastern lowland gorillas are found in eastern DRC. **Deforestation** and **hunting** now threaten lowland gorillas throughout their range.

The mountain gorilla has been intensely studied in the field, notably by George Schaller and Dian Fossey, upon whose life the film *Gorillas in the Mist* is based. This endangered subspecies is found in the misty mountains of eastern Zaire, Rwanda, and Uganda at altitudes of up to 9,000 ft (3,000 m) and in the Impenetrable Forest in southwest Uganda. Field research has shown these powerful primates to be intelligent, peaceful and shy, and of little danger to humans.

A silverback male gorilla. (Photograph by Jerry L. Ferrara. Photo Researchers Inc. Reproduced by permission.)

Other than humans, gorillas have no real predators, although leopards will occasionally take young apes. Hunting, **poaching** (a mountain gorilla is worth $150,000), and **habitat** loss are causing gorilla populations to decline. The shrinking forest refuge of these great apes is being progressively felled in order to accommodate the ever-expanding human population. Mountain gorillas are somewhat safeguarded in the Virunga Volcanoes **National Park** in Rwanda. Their protection is funded by strictly controlled small-group gorilla-viewing tourist experiences that exist alongside long-term field research programs. Recent population estimates are 10,000–35,000 (with 550 in captivity) western lowland gorillas, 4,000 (with 24 in captivity) eastern lowlands gorillas, and 620 mountain gorillas.

Grand Staircase-Escalante National Monument

The Grand Staircase-Escalante National Monument, encompassing 1.7 million acres (700,000 ha) of public lands on the Colorado Plateau in south-central Utah, was created on September 18, 1996, by presidential proclamation under authority of the Antiquities Act of 1906 (34 Stat. 225, 16 U.S.C. 431). The **U.S. Department of the Interior** had first recommended the creation of the Escalante National Monument along the Colorado and Green Rivers in 1936. In 1937, Capitol Reef National Monument was established in the area northeast of the Escalante Canyons along the upper portion of Waterpocket Fold. In 1941, the **National Park Service** studied the basin in conjunction with a comprehensive study of **water resources** in the **Colorado River** Basin. The study, published in 1946, identified the Aquarius Plateau/Escalante River Basin as "a little known, but potentially important **recreation** area." The area was recognized as a strategic link between the national parks in southwestern Utah and the canyon country of southeastern Utah.

A national monument is the designation given to a particular area to protect "historic landmarks, historic and prehistoric structures, and objects of historic or scientific interest that are situated upon the lands owned or controlled by the government of the United States." President **Theodore Roosevelt** exercised this authority to ensure protection for the Grand Canyon. More than 100 national monuments have been established by Presidents over the past 90 years, including Zion, Bryce Canyon, Glacier Bay, Death Valley, and Grand Teton. The Grand Staircase-Escalante National Monument was dedicated from the Grand Canyon **National Park** in Arizona, and no elected official from Utah was at the ceremony because of the controversy in Utah about the monuments designation.

The Grand Staircase-Escalante National Monument was created to preserve geological, paleontological, archaeological, biological, and historical features of the area. Geological features include clearly exposed stratigraphy and structures. The sedimentary rock layers are relatively undeformed and unobscured by vegetation, providing a view to understanding of the processes of the formation of the earth. A wide variety of geological formations in colors such as red, pink, orange, and purple have been exposed by millennia of **erosion**. The monument contains significant portions of a vast geological stairway, which was named the Grand Staircase by the geologist Clarence Dutton. This stairway rises 5,500 ft (1,678 m) to the rim of Bryce Canyon in an unbroken sequence of cliffs and plateaus. The monument also includes the canyon country of the upper Paria Canyon system, major components of the White and Vermillion Cliffs and associated benches, and the Kaiparowits Plateau. The Kaiparowits Plateau includes about 1,600 mi^2 (2, 574 km^2) of sedimentary rock and consists of south-to-north ascending plateaus or benches, deeply cut by steep-walled canyons. Naturally burning underground **coal** seams have changed the tops of the Burning Hills to brick-red. A major landmark, the East Kaibab Monocline, or Cockscomb, is aligned with the Paunsaugant, Sevier, and **Hurricane** Faults, which may indicate that it may also be a fault at depth. The Circle Cliffs, which features intensively colored red, orange, and purple mounds and ledges at the base of the Wingate Sandstone Cliffs, are one of the most distinctive landscapes of the Colorado Plateau. Inclusion of part of the Waterpocket Fold completes the protection of this geologic feature, which was begun with the establishment of the Capitol Reef National Monument in 1936. There are many arches and natural bridges within the monument boundaries, including the 130-ft (39.4-m) high Escalante Natural Bridge, with a 100-ft (30.3-m) span and the Grosvenor Arch, a double arch. The upper Escalante Canyons, in the northeastern part of the monument, include several major arches and bridges and geological features in narrow, serpentine canyons, where erosion has exposed sandstone and shale deposits in colors of red, maroon, brown, tan, gray, and white.

Paleontological features include petrified wood, such as large unbroken logs more than 30 ft (9 m) in length. The stratigraphy of the Kaiparowits Plateau provides one of the best and most continuous records of the paleontology of the late Cretaceous Era. Fossils of marine and **brackish** water mollusks, turtles, **crocodiles**, lizards, dinosaurs, fishes, and mammals (including a marsupial primitive mammal) have been recovered from the Dakota, Tropic Shale, and Wahweap Formations and the Tibbett Canyon, Smoky Hollow, and John Henry members of the Straight Cliffs Formation.

Archeological inventories show extensive use of places within the monument by Native American cultures. Recorded sites include rock art panels, occupation sites, rock shelters, campsites, and granaries.

Historical evidence indicates that the monument was occupied by both Kayenta and Fremont agricultural cultures for a period of several hundred years centered around A.D.

1100. The area has been used by modern tribal groups, including the Southern Paiute and the Navajo. In 1872, an expedition of John Wesley Powell did initial mapping and scientific field work in the area. The expedition discovered the Escalante River, naming it in honor of the Friar Silvester Valez de Escalante expedition of 1776. The Escalante River Canyons have been a major barrier to east-west travel in the region in historic times. The river is presently bridged only at its upper end. Early Mormon pioneers left many historic objects, including trails, inscriptions, ghost towns such as the Old Paria townsite (built in 1874 and abandoned in 1890), rock houses, cowboy camps, and they built the Hole-in-the Rock Trail in 1879–1880 as part of their colonization activities. Sixty miles (96.6 km) of the Hole-in-the-Rock Trail are within the monument, as well as Dance Hall Rock, used by Mormon pioneers for meetings and dances, and now a National Historic Site.

As a biological resource, the Grand Staircase-Escalante National Monument spans five life zones, from low-lying **desert** to **coniferous forest**. Remoteness, limited travel corridors, and low visitation have helped to preserve the ecological features, such as areas of relict vegetation, many of which have existed since the Pleistocene. Pinon-juniper communities containing trees up to 1,400 years old and relict sagebrush-grass park vegetation can be found on No Man's Mesa, Little No Man's Mesa, and Four Mile Bench Old Tree Area. These relict areas can be used to establish a baseline against which to measure changes in community dynamics and biogeochemical cycles in areas impacted by human activity. The monument contains an abundance of unique isolated communities such as hanging gardens and canyon bottom communities, with riparian plants and their pollinators; tinajas, which contain tadpoles, fairy and clam shrimp, amphibians, and snails; saline seeps, with plants and animals adapted to highly saline conditions; dunal pockets, with **species** adapted to shifting sands; rock crevice communities, consisting of slow-growing species that can thrive in extremely infertile sites; and cryptobiotic crusts, which stabilize the highly **erodible** desert soils and provide nutrients for plants. The **wildlife** of the monument is characterized by a diversity of species, where both northern and southern **habitat** species intermingle. Mountain lions, bears, and desert bighorn sheep, as well as over 200 species of birds, including bald eagles and peregrine falcons, can be found within the monument. The wildlife concentrates around the Paria and Escalante Rivers and other riparian areas.

The Secretary of the Interior, through the **Bureau of Land Management** (BLM), which in the past has been responsible for the public lands included within the monument area, will manage the monument. This is the first national monument that will be managed by the BLM. The BLM will develop a management plan to address measures necessary to protect the scientific and historic features within the monument by three years after the date of establishment of the monument. The BLM will consult with state and local governments, other federal agencies, and tribal governments to prepare the **land use** plan.

The boundaries of the Grand Staircase-Escalante National Monument were drawn to exclude as much private land as possible, as well as the towns of Escalante, Boulder, Kanab, and Tropic. The national monument designation applies only to Federal land and not to the approximately 9,000 acres (3,644 ha) of private land remaining within the boundaries of the monument. Private landowners continue to have existing rights of access to their property. The landowners may participate in land exchanges with the BLM to trade land within the monument for land of equal value outside the area. The State of Utah owns about 180,000 acres (73,800 ha) of isolated, 640-acre (262 ha) sections of school lands within the boundaries of monument. The State will be allowed to exchange these isolated school lands for federal lands of equal value outside the monument boundaries. All federal lands were withdrawn from sale or leasing under the **public land** laws upon designation as a national monument. The designation also prohibited the issuance of any new mineral leases in the area, including new claims made under the Mining Law of 1872. Existing uses under federal or state laws, such as **hunting**, camping, travel, hiking, backpacking, and other recreational activities, as well as grazing permits, continue under current policies and rules. The proclamation did not reserve water or make any federal **water rights** claims. As part of the management plan, the BLM will evaluate the extent to which water is necessary for the care and management of objects of the monument and the extent to which further action may be necessary under federal or state law to ensure availability of water.

Grasslands

Grasslands are environments in which herbaceous **species**, especially grasses, make up the dominant vegetation. Natural

grasslands, commonly called **prairie**, pampas, shrub steppe, palouse, and many other regional names, occur in regions where rainfall is sufficient for grasses and forbs but too sparse or too seasonal to support tree growth. Such conditions occur at both temperate and tropical latitudes around the world. In addition, thousands of years of human activity—clearing pastures and fields, burning, or harvesting trees for materials or fuel—have extended and maintained large expanses of the world's grasslands beyond the natural limits dictated by **climate**. Precipitation in temperate grasslands (those lying between about 25 and 65 degrees latitude) usually ranges from approximately 10–30 in (25–75 cm) per year. At tropical and subtropical latitudes, annual grassland precipitation is generally between 24 and 59 in (60 and 150 cm). Besides its relatively low volume, precipitation on natural grasslands is usually seasonal and often unreliable. Grasslands in **monsoon** regions of Asia can receive 90% of their annual rainfall in a few weeks; the remainder of the year is dry. North American prairies receive most of their moisture in spring, from snow melt and early rains that are followed by dry, intensely hot summer months. Frequently windy conditions further evaporate available moisture.

Grasses (family Gramineae) can make up 90% of grassland **biomass**. Long-lived root masses of perennial bunch grasses and sod-forming grasses can both endure **drought** and allow asexual reproduction when conditions make reproduction by seed difficult. These characteristics make grasses especially well suited to the dry and variable conditions typical of grasslands. However, a wide variety of grass-like plants (especially sedges, Cyperaceae) and leafy, flowering forbs contribute to species richness in grassland **flora**. Small shrubs are also scattered in most grasslands, and **fungi**, mosses, and **lichens** are common in and near the **soil**. The height of grasses and forbs varies greatly, with grasses of more humid regions standing 7 ft (2 m) or more, while **arid** land grasses may be less than one-half meter tall. Wetter grasslands may also contain scattered trees, especially in low spots or along stream channels. As a rule, however, trees do not thrive in grasslands because the soil is moist only at intervals and only near the surface. Deeper tree roots have little access to water, unless they grow deep enough to reach **groundwater**.

Like the plant community, grassland animal communities are very diverse. Most visible are large herbivores—from American **bison** and elk to Asian camels and horses to African kudus and wildebeests. Carnivores, especially **wolves**, large cats, and bears, historically preyed on herds of these herbivores. Because these carnivores also threatened domestic herbivores that accompany people onto grasslands, they have been hunted, trapped, and poisoned. Now most wolves, bears, and large cats have disappeared from the world's grasslands. Smaller species compose the great wealth of grassland **fauna**. A rich variety of birds breed in and around ponds and streams. Rodents perform essential roles in spreading seeds and turning over soil. Reptiles, amphibians, insects, snails, worms, and many other less visible animals occupy important niches in grassland ecosystems.

Grassland soils develop over centuries or millennia along with regional vegetation and according to local climate conditions. Tropical grassland soils, like tropical forest soils, are highly leached by heavy rainfall and have moderate to poor **nutrient** and contents. In temperate grasslands, however, generally light precipitation lets nutrients accumulate in thick, organic upper layers of the soil. Lacking the acidic leaf or pine needle litter of forests, these soils tend to be basic and fertile. Such conditions historically supported the rich growth of grasses on which grassland herbivores fed. They can likewise support rich grazing and crop lands for agricultural communities. Either through crops or domestic herbivores, humans have long relied on grasslands and their fertile, loamy soils for the majority of their food.

Along a moisture gradient, the margins of grasslands gradually merge with moister savannas and woodlands or with drier, **desert** conditions. As grasslands reach into higher latitudes or altitudes and the climate becomes to cold for grasses to flourish, grasslands grade into **tundra**, which is dominated by mosses, sedges, willows, and other cold-tolerant plants.

Grazing on public lands

Grazing on public lands is the practice of raising livestock on land that is not privately owned. Livestock such as cattle and sheep eat forage (grass and other herbage) on the **public land**. Through the twentieth century and into the twenty-first, ranchers grazed livestock on federal and state public land in the western states.

The western livestock industry developed during the decades after the Civil War, according to a **Bureau of Land Management** (BLM) report. People headed west where the land was open. A prospective rancher just needed a headquarters, some horses and cowboy employees. Some ranches consisted of a dugout shelter for the people and a horse corral.

Livestock grazed on open land called the range. When livestock ate all the forage in one area, the rancher moved the herd and headquarters to another area. By 1870, there were 4.1 million beef cattle and 4.8 million sheep in 17 states, according to BLM. Thirty years later, there were 19.6 million cattle and 25.1 million sheep. As the number of livestock increased, the range became crowded and there was less forage.

The twentieth century opened with discussion in Congress about how to regulate use of public lands. After years of debate, Congress approved the **Taylor Grazing Act** in 1934. The act established a permit requirement and "significantly reduced" the number of ranchers and livestock, according to BLM. A portion of fees was allocated to the grazing district for improvements like fencing.

The act only addressed grazing as a **land use**. That policy changed with the approval of the 1976 **Federal Land Policy and Management Act**. FLPMA stated that federal public lands and their resources would be managed for multiple uses that "best meet the present and future needs for the American people."

Passage of the act reflected concerns about environmental protection and **conservation**. At the same time, the increase in population brought more demand for recreational uses of public land. In the years since the passage of FLPMA and environmental protection laws, the land-use debate intensified.

Federal public lands include the 264 million acres managed by BLM in 12 western states and the 191 million acres of United States **Forest Service** land in 44 states. Federal grazing permits were issued by those jurisdictions, the **National Park Service**, and the **Fish and Wildlife Service**. BLM manages about half of the 270 million acres where grazing is allowed. Ranchers pay a fee called an animal unit month (AUM). This is based on the monthly amount of forage needed to sustain one cow and her calf, one horse, or five sheep or goats. The AUM in 2002 was $1.43. Opponents called the fee a government subsidy. They estimated an AUM of $11 for grazing on private land.

BLM records for fiscal year 2001 showed 15,643 operators (ranchers) of cattle, yearling, and buffalo; 1,232 operators of horses and burros; and 1,225 operators of sheep and goats. Those figure were not a total count since some operators may have raised more than one type of livestock. The BLM figures were from the administrative jurisdiction of Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, and Wyoming. California BLM administers some land in Nevada, and Montana administers all public land in North and South Dakota.

Within those states, active AUMs totaled 11.3 million as of November 29, 2001, according to BLM. Livestock cause more damage to public land than the chainsaw or the bulldozer, according to anti-grazing activists. Damage includes trampled vegetation, **soil** damage, **water pollution**, and the spread of invasive weeds, according to grazing opponents.

The beef and sheep industries are represented by the **Public Lands Council** (PLC), an organization that said grazing helped to preserve open space. PLC said that opponents incorrectly blamed ranchers for **environmental degradation**. According to PLC, research indicated that conservation goals on public land were easier to achieve when grazing was properly managed. Livestock managers could make improvements that would not be done if grazing was prohibited.

Grazing opponents disagreed and used various methods to limit grazing. Lawsuits claimed that grazing violated environmental regulations. Successful cases include the 1998 removal of livestock from the Gila River Basin in Arizona and New Mexico. The ruling was based on the **Endangered Species Act** and the protection of the spotted owl and other **species**.

Furthermore, activists tried to buy leases. They urged ranchers to end leases by retiring their permits. Another solution was proposed in 2002 by the National Public Lands Grazing Campaign. An umbrella group of various organizations, NPLGC wanted federal law changed to allow the voluntary retirement of grazing permits. The federal government would pay $175 per AUM to buy out leases. NPLGC said the plan would cost an average of $13.45 per acre.

The livestock industry rejected the plan. PLC said in April of 2002 that the plan could cost taxpayers more than $3.2 billion. Plan supporters countered that grazing "subsidies" cost taxpayers up to $460 million annually. The federal government had not taken action on the proposal as of May of 2002.

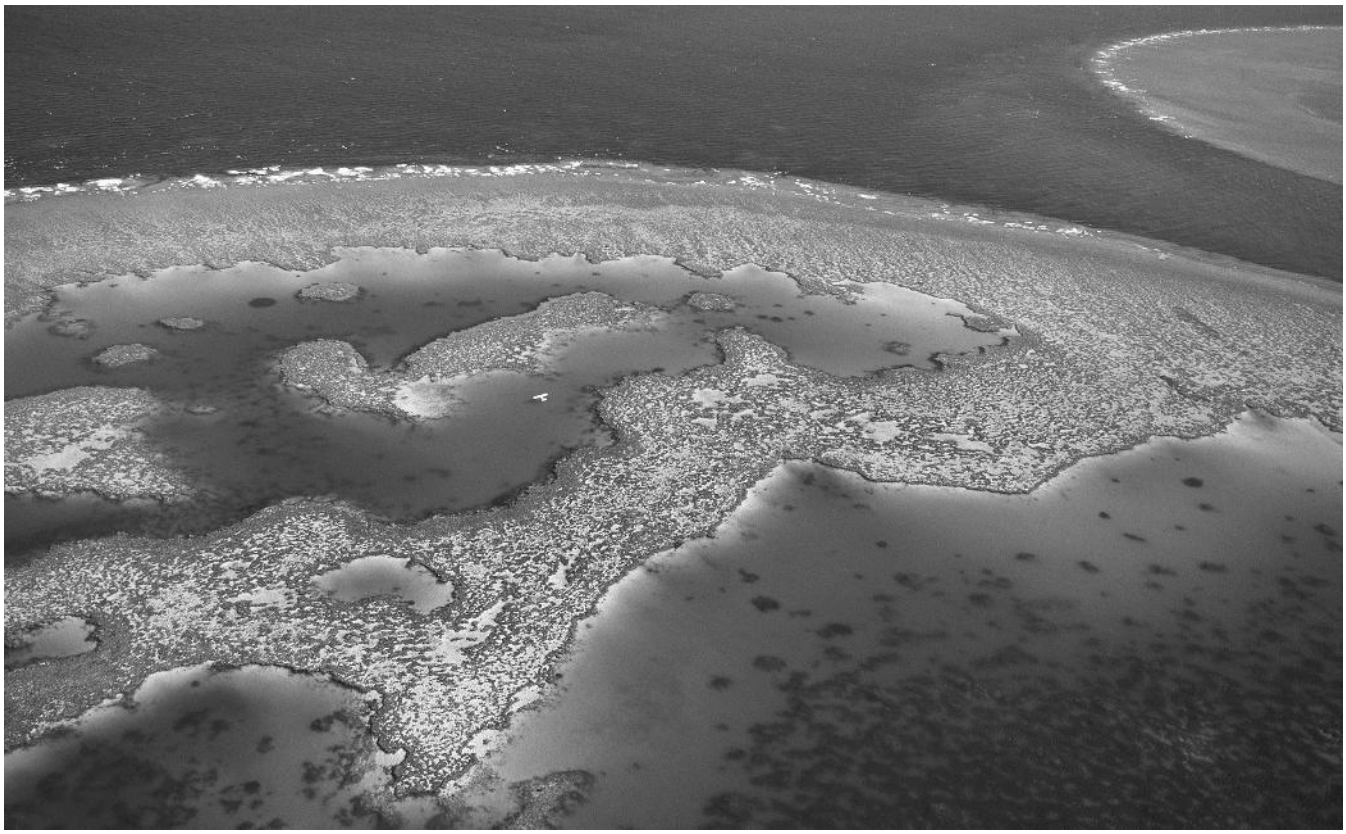
Great Barrier Reef

The Great Barrier Reef, located in the Coral Sea off the eastern coast of Queensland in northeastern **Australia**, consists of more than 2,800 reefs that range in size from 1 hectare to over 10,000 hectares in area. As the largest reef in the world, the Great Barrier Reef is 1,250 mi (2,011 km) in length, extending from a point near McKay, Queensland in the **south** to the Torres Strait in the north, which lies between Australia and New Guinea. The Reef is 45 mi (72 km) across at its widest point, with a total area of more than 300,000 square kilometers. Approximately 20% of the reefs are submerged reefs or shoals, while about 26% are fringing reefs around continental islands or along the mainland coast. The remaining reefs are shelf reef platforms. Water depths range from 65.6–98 ft (20–30 m) in lagoonal areas to 131–197 ft (40–60 m) between the reefs on the outer shelf. Starting in the south near the Tropic of Capricorn, the Great Barrier Reef is a wide scattering of reefs about 186 mi (300 km) out from the coast; moving north the Reef becomes more continuous and is within 10–12 mi (16–19 km) of the coast, with a few individual reefs in the inner **lagoon** (the area between the reef and the coast). North of Cairns the reef is almost a continuous barrier between the coast and the Coral Sea. Drilling has indicated that in places the reef is over 1,640.5 ft (500 m) thick.

At the end of the last **ice age**, about 20,000 years ago, the sea level was about 394 ft (120 m) lower than it is today, and dry land extended from the present day coast to the location of today's outer Barrier Reef. As the ice melted, the sea rose, and by 13,000 years ago the coastal plain had become a submerged continental shelf. Corals and reefs grow best where there is water movement, so the reefs tended to form on submerged hills in the **flooding** coastal plain. By 6000 to 7000 years ago, the sea had reached its present level, and the reef began to assume its present shape. The Spanish mariner Luis Vaáez de Torres was the first European known to have sailed the northern reef, but the Spanish kept the route a secret to protect their route between Europe and the Orient. The Reef was explored and charted by Captain James Cook, whose ship in 1770 ran aground on the reef that now is called the Endeavor, after the name of his ship.

The Great Barrier Reef provides homes and shelter for a wide diversity of life. The Great Barrier Reef is home to corals, which form the reefs, **dolphins** and **whales**, six **species** of **sea turtles**, more than 1,500 species of fish, 4,000 types of mollusks, 500 species of seaweed, and more than 200 species of birds. The corals that make up the Reef consist of individual living coral polyps, which as they divide in a process called budding, form colonies in fan, antler, brain, and plate shapes. Each polyp, which is a tiny jelly-like, sack-like animal with a mouth surrounded by tentacles, lives inside a shell of aragonite, a type of calcium carbonate that is the hard shell typically recognized as coral. The polyps are joined together to form a colony. Coral polyps obtain food by catching **plankton** in their tentacles as well as deriving nutrients from symbiotic algae, the zooxanthellae, that live within their tissues. These zooxanthellae produce nutrients through **photosynthesis**, which are then available for use by the coral. Association with the algae allow corals to build skeletons three times faster in the light than in the dark, and faster than storms and waves can break it down. **Coral bleaching** occurs when stressed corals expel the zooxanthellae and turn white, or bleached. If the zooxanthellae do not return to the coral, the coral will die.



Every year about one-third of the 350 species of coral reproduce sexually during a mass spawning event. Spawning occurs in most of the inner reefs around November and in the outer reefs in December. The spawning occurs at night, up to six days after the full moon. Eggs and sperm are released into the water, where they combine to form a free-swimming larval stage.

The Great Barrier Reef is completely within the tropics. The **climate** of the Reef is a typical **monsoon** weather pattern, which consists of strong south-easterly winds dominating during the dry winter months and weaker variable winds occurring during the summer wet season. Both air and sea temperatures exhibit seasonal variations. Mean sea temperatures in inshore areas exhibit a range of temperatures of 69.8°F (21°C) in July and August to 86°F (30°C) in January and February. Temperatures on offshore reefs exhibit less seasonal difference, varying from 73.4°F (23°C) in winter to 82°F (28°C) in summer.

There are two types of islands along the Great Barrier Reef. The larger islands, such as those of the Whitsunday group, are the tops of submerged mountains that at one time were high points of a range running along the coast. These islands have vegetation similar to the mainland. Some of these islands that have fertile soils and are affected by heavy monsoonal rains are covered with rain forests. Other islands are isolated low-lying coral cays. Cays are formed when coral grow to levels that are higher than sea level, even at low tide. Coral can only survive a few hours out of water. The dead coral on the cays is worn down and broken off by waves and storm action. Eventually the coral debris is ground into sand. Through time the sand stabilizes, seabirds start to nest, and hardy vegetation begins to grow. Decomposing plant materials and bird droppings change the sand into a more developed **soil**, providing an **environment** for a wider diversity of plant life. Cays are found more frequently on inner reefs in the Great Barrier Reef, where waves and currents are less strong than on reefs further away from the coastline. However, vegetated cays are not sufficiently stable to withstand severe weather, such as storms and cyclones.

Comprehensive protection of the Great Barrier Reef was accomplished in 1975 by the formation of the Great

An aerial view of a portion of the Great Barrier Reef. (Photograph by Yann Arthus-Bertrand. Corbis-Bettmann. Reproduced by permission.)

Barrier Reef Marine Park, administered by the Great Barrier Reef Marine Park Authority (GBRMPA). Over 98% of the area, with the exception of a few coastal areas, is now included within the Marine Park. Drilling and mining for minerals within all areas of the Marine Park is forbidden. In 1981, in recognition of its outstanding natural heritage value, most of the Great Barrier Reef area was added to the World Heritage List by the United Nations Education, Scientific, & Cultural Organization (**UNESCO**). The Great Barrier Reef World Heritage Area is the largest of the world's over 550 World Heritage Areas. In addition to the **coral reef** area, the Great Barrier Reef World Heritage Area also contains the continental slope, the inter-reefal areas, and the Great Barrier Reef lagoon.

The Great Barrier Reef Marine Park has been classified into 70 bioregions, which are areas of differing marine **biodiversity** with plant and animal communities that, together with physical features, are significantly different than the surrounding areas and the rest of the Marine Park. Based on these bioregions, the GBRMPA has divided the Marine Park into six zones: (1) the Preservation Zone, which includes areas that are intended to be kept completely untouched; (2) the Scientific Research Zone, which includes areas set aside exclusively for scientific research; (3) the Marine **National Park** A Zone, which includes areas where recreational use (i.e., fishing with one line and one hook) is permitted, but **commercial fishing** is not permitted; (4) the General Use B Zone, where reasonable recreational and commercial uses are permitted, but trawling and shipping are prohibited; and (5) the General Use A Zone, where all reasonable uses are permitted, including trawling and shipping, but mining, **oil drilling**, commercial spear fishing and fishing with scuba equipment are not permitted.

More than two million people a year visit the reef, generating more than $AU1 billion in tourism dollars. Tourists visit the reef using private charter boats, regular scheduled daily cruises, seaplanes, air charter, and helicopter flights. They view the reefs through reef walks, glass bottom or semi-submersible boats, snorkeling, or scuba diving.

The Great Barrier Reef is sensitive to climate changes and to changes in patterns of water movement. In 1998

scientists announced that about 60% of the reef had been affected by coral bleaching due to increasing sea temperatures and fresh water flooding.

The Reef is also susceptible to physical damage. Human damage to the Great Barrier Reef has been occurring due to carelessness, where people walk on the reefs, drop anchors onto them, drag diving gear over them, break them into pieces to take as souvenirs, and knock into and ground boats onto them.

Since the 1960s, during periodic outbreaks, the Crown of Thorns starfish has been destroying corals that make up the reef. The Crown of Thorns is a large, thorny, brown-colored starfish. The starfish eats coral by turning its stomach out through its mouth, in a process called stomach eversion, wraps the stomach around a coral, and secretes an **enzyme** to digest the living coral polyps. When the stomach is drawn back in, all that is left is the limestone coral skeleton. This skeleton becomes covered with green algae and other types of encrusting plants and animals, which give the coral skeleton a dull, gray appearance. Some types of corals become infested with boring organisms. During periods of rough weather (e.g., during a **cyclone**), the dead colony and the newly attached organisms may collapse. Some scientists feel that outbreaks of the Crown of Thorns starfish may be a natural part of the lifecycle of the reef. By feeding on fast-growing species of corals, the starfish may act to preserve coral diversity, for fast-growing populations, if left unchecked, could dominate the reef.

Water quality has been identified by the Great Barrier Reef Marine Park Authority as a critical management issue, as **pollution** by sediments, toxic metal and organic contaminants, **oil spills**, and pesticides, can potentially harm the Reef. Sewage **discharge** is regulated in the Marine Park area, with tertiary treatment (i.e., **nutrient** reduction) required before marine discharge; alternatively secondary or tertiary treated **wastewater** can be land applied with minimal marine discharge. However, the primary water quality concern is nutrient **loading** from inshore ecosystems. Programs are being developed to reduce nutrient inputs through regulation of discharges, integrated catchment management, improved land management practices, and wetland protection.

Great Lakes

The advance and retreat of glaciers over millions of years scraped and scoured the Great Lakes basins until they attained their present form about 10,000 years ago. Forming the largest system of inland lakes in the world, the Great Lakes have a surface area of 94,200 mi^2 (244,000 km^2) and a volume of more than 28 trillion yd^4 (22,000 km^3) of water, 20 percent of the world's surface freshwater.

Lake Superior, with more than 31,660 mi^2 (82,000 km^2) of water, has the largest surface area of freshwater on earth. Lake Huron, the world's fifth largest lake, is at the same elevation and about the same size as Lake Michigan, the world's sixth largest lake. The two are joined by the narrow, deep Straits of Mackinac. Their accumulated waters empty into the St. Clair River which flows into the 460 mi^2 (1,190 km^2) Lake St. Clair. The water continues its flow into the Detroit River before entering **Lake Erie**, the eleventh largest lake in the world. It is the oldest, shallowest, busiest, and most eutrophic of the Great Lakes. The waterway continues on into the Niagara River, then to the famous Niagara Falls, where the water descends a total of 325 ft (99 m) before it empties into the last Great Lake, Ontario. The fourteenth largest lake on earth, Lake Ontario is the smallest in surface area but the second deepest of the Great Lakes. It discharges into the St. Lawrence River, which flows into the Atlantic Ocean at the Gulf of St. Lawrence.

The first European explorers discovered a great variety of native fish. Approximately 153 **species** were eventually identified before human interference disrupted the **ecosystem**, first by **overfishing**, and then by lumbering and industrial development. As many species of fish have disappeared, about twenty new species have been introduced. Some, such as the Pacific salmonids, carp, and smelt, were introduced intentionally. Others, such as the sea lamprey, alewife, and **zebra mussel**, gained access through the Erie and Welland Canals or by release with the ballast water of vessels transporting other cargo.

Today, lake trout, burbot, and whitefish are the principal catches of a once extraordinarily rich fisheries enterprise. Despite the decline in the quality and numbers of suitable fish, sport and **commercial fishing** are still vital Great Lakes industries. The sport fishery consists primarily of coho, chinook **salmon**, steelhead trout, walleye, and perch. They now attract about five million anglers annually with a regional economic benefit of about $2 billion.

Besides directly water-related activities, presently, one-fifth of the industry and commerce of the United States is located in the Great Lakes catchment basin because of

the availability of abundant cheap and clean freshwater and accessible, efficient water **transportation** among the lakes and to the oceans. As a consequence, **pollution** has taken some obvious as well as more subtle forms. Using the lakes as a cheap sewage disposal site for shoreline city populations began in the early seventeenth and eighteenth centuries and continued until the early 1970s. To improve the quality of the Great Lakes, the first efforts concentrated on preventing or removing conventional pollutants such as **phosphates**, suspended solids, and **nitrogen**.

More deadly toxic contaminants often are not visible and so initially attracted less attention. Over the past fifty years municipal and industrial wastes so polluted the waters, especially the lower Great Lakes, that, beginning in the middle 1960s organochlorides were identified as serious contaminants. Fish were collecting, through **bioaccumulation**, relatively large concentrations of agricultural pesticides such as DDT and dieldrin as well as the industrial chemical polychlorinated biphenyl (PCB) in their tissues. These were passed into the human **food chain/web**. By 1980 more than 400 organic and **heavy metals** contaminants had been found in fish, and fishermen were warned to limit their consumption. The effects of pollutants are seen primarily at the tops of food chains and are usually discovered through changes in population levels of predator species. Organochlorines and methylated **mercury**, for example, bioaccumulate to levels that may cause reproductive failures in fish-eating birds and animals such as cormorants, eagles, and mink.

Between 1969 and 1972 legislation was enacted in several states bordering the Great Lakes basin to restrict or ban the use of dieldrin, DDT, PCBs, mercury and other toxic **chemicals**. After **point source** discharges were regulated, lake trout and chub, especially in Lake Michigan, showed dramatic declines in these contaminants. By 1978–79, however, the fish contaminant declines were only slight; or the levels remained relatively constant, reflecting airborne inputs as well as the remobilization of contaminants from the **sediment**.

This problem is likely to continue because the turnover rates of the Great Lakes are very slow; and mercury, PCBs and the pesticides DDT, dieldrin and **chlordane** are very resistant to degradation in the **environment**. Also, these compounds continue to enter the Great Lakes ecosystem from highly diffuse nonpoint sources such as airborne deposition, agricultural and **urban runoff**, remobilization from the sediments, **leaching** from municipal and industrial landfills, municipal and industrial discharges, and illegal dumping. *See also* Agricultural chemicals; Agricultural pollution; Great Lakes Water Quality Agreement; Heavy metals and heavy metal poisoning; Industrial waste treatment; Methylation; Water pollution

Great Lakes Water Quality Agreement (1978)

The **Great Lakes Water Quality** Agreement of 1978 amended and strengthened the International Great Lakes Water Quality Agreement between Canada and the United States, which was signed in 1972. The original agreement established a framework for research, clean-up, and **pollution control** based on goals determined by the two nations. The existing **International Joint Commission**, in cooperation with the newly-created International Great Lakes Water Quality Board, was to oversee the implementation of the agreement. Chief goals of the agreement were to reduce the amount of **phosphorus** being dumped into the lakes by 50 percent, to require all municipal **sewage treatment** plants to be at the secondary level (removing nutrients such as phosphorous and **nitrogen**), and to control toxic **water pollution**.

The impetus for action in 1972, and again in 1978, was the decreasing water quality in the Great Lakes. Two incidents best symbolized this to the nation. First, the massive algal blooms in **Lake Erie**, due to eutrophication, led many commentators to declare that the lake was dead. And second, when the **Cuyahoga River** in Cleveland caught fire in 1969, it provided a clear visual message to the rest of the country about the state of **pollution** in the Great Lakes. Perhaps not as visible, but just as serious, the Great Lakes were also suffering from toxic chemical pollution, which was a problem for water use, and also for sports and recreational fishing. Limits, and in some cases, bans, were placed on how much fish from the lakes could be consumed.

The 1978 Agreement substantially strengthened the 1972 accord. The new agreement focused especially on toxic pollutants and phosphorous, the chief **nutrient** responsible for eutrophication in the Great Lakes. A stricter definition of a **toxic substance** was included, as well as specific water quality objectives for certain **heavy metals**, polychlorinated biphenyl (PCB), and pesticides, and a list of hundreds of hazardous and potentially hazardous materials. Phosphorous entering the lakes would be reduced further in certain lakes,

primarily by improved **municipal solid waste** plants. Additional sections of the agreement dealt with pollution resulting from airborne **toxins**, **dredging**, shipping, and **nonpoint source** pollution. A contingency plan between the two nations to respond to spills or other severe pollution episodes was also to be created. The Agreement is an Executive Agreement with no force of law in either Canada or the United States. Rather, each nation must depend on existing laws to meet these joint goals.

The Great Lakes Critical Programs Act, passed in 1990, was designed to increase the efforts of the **Environmental Protection Agency** (EPA) and the states in cleaning up the Great Lakes. Evaluations of the 1978 Agreement indicated that neither the EPA nor the states had been putting sufficient effort into the implementation of the necessary programs.

By the middle 1990's, significant progress had been made on reducing phosphorous pollution and improving municipal sewage treatment by building new plants and improving existing plants. Phosphorous loadings were below 1978 target loads for Superior, Huron, and Michigan, and at or near target loads for Erie and Ontario. Hence, this aspect of the water quality agreement has largely been achieved. There has also been significant improvement on **point source** pollution of toxic **chemicals** such as PCBs. Toxic substances in the lakes remain a major problem due to **air pollution**, **runoff** (non-point source pollution), and releases from already contaminated sediments. For instance, the source of over 75% of the PCBs entering Lake Superior and 95% of the lead entering the Great Lakes is air pollution. In 1995, Canada and the United States agreed to develop a coordinated binational strategy to virtually eliminate persistent toxic substances from the Great Lakes Basin. That same year, the EPA launched the Great Lakes Water Quality Initiative as a framework for achieving that goal. *See also* Agricultural runoff; Chemical spills; Heavy metals and heavy metal poisoning; Oil spills

Great Smoky Mountains

The Great Smoky Mountains (GSM) **National Park** covers approximately 543,400 acres (220,000 ha) of western North Carolina and southeastern Tennessee, making the park the single largest **wilderness** area in the eastern United States. The mountains received their name from the Cherokee for the smoke-like clouds which frequently shroud their peaks and the grey-green **haze** of the wooded slopes. In early fall, this grey-green haze becomes a blaze of autumnal colors. The GSM are known for their large stands of some of the world's best remaining examples of temperate **deciduous forest**, and for their "balds" or treeless mountain tops. The park's size, scenic beauty, and geographical proximity to large population centers are features that contribute to attracting more visitors annually than any other national park (including the somewhat better-known Yellowstone, Yosemite, and Grand Canyon National Parks).

The GSM are situated in what had been one of the least accessible areas of the eastern United States. Natural barriers contributed to relatively low levels of development and exploitation through the eighteenth and nineteenth centuries. GSM National Park was authorized in 1926. Land purchase (funded in part by a five million dollar donation from foundations associated with the Rockefeller family) began in 1930 and was established through an act of Congress in June of 1934. The Park was formally dedicated by President Franklin D. Roosevelt in 1940. In 1976, the Park was recognized as a **biosphere reserve**, and in 1983 the GSM were selected as a World Heritage Site.

The GSM contain several of the highest mountain peaks in the United States east of the Mississippi River. The Park's Mt. Guyot, Mt. Chapman, and Mt. Leconte all tower over 6,000 ft (1,830 m). At 6,643 ft (2,025 m), Clingman's Dome, on the Tennessee side, is the highest point in the Park, as well as the crest of the Appalachian Trail. This peak was named after General Thomas L. Clingman, a soldier and scientist who, while exploring the area with Arnold Guyot in the late nineteenth century, was the first to measure the summit's elevation.

Among the oldest mountains in the world, the GSM also contain some of the oldest rock strata in the eastern United States. Sheetlike layers of slate (a fine-grained rock originally formed from mud **sediment**) create jagged outcrops of spectacularly-angled rock, glinting in areas where mica deposits (a sparkling mineral formed when slate is heated) show through to the surface. The slate that makes up much of the jagged central ridge line tells the story of how the mountains were formed by repeated elevations rather than by one single geological event. The bedrock ranges in age from about 600 million–1 billion years and exhibits a range of different characteristics owing to metamorphoses caused by the heat and violence of geological shifts.

More than 148,200 acres (60,000 ha) of GSM National Park are pristine or primitive. Early in the summer,

the characteristic "balds" of the GSM (clear, treeless patches on the summits) are brightened by rhododendron blooms around their peripheries. Several varieties of spruce, buckeye, birch, hemlock, dogwood are also common. The abundant sunshine and frequent rain of the region help support over 1,500 **species** of flowering plants, including eight species of trillium, 32 species of violets, and 29 species of orchids. During the last **ice age**, the highlands were a refuge for northern plant species displaced by the continental ice sheet. Remnants of some of these species, including red spruce and Fraser fir, can still be found at the higher elevations but virtually nowhere else at this latitude. The Park contains the largest virgin forests of red spruce and balsam fir, and the finest virgin hardwood forests left in the United States. Indeed, the slopes of the GSM may support more virgin timber than the rest of the eastern United States combined. In the fall, when the green chlorophyll in deciduous leaves begins to break down, these forests put on a spectacular show of color. Fall colors generally peak between October 15–25, when up and down the mountains may be seen the brilliant reds of maples, golden yellow of beech, and the deeper hues of oaks and more southerly species. But Park visitation also peaks at this time, and those visitors who use the main roads through the Park frequently find themselves in bumper-to-bumper traffic jams with other nature-lovers.

Despite the huge annual invasion of tourists and hikers, GSM National Park nevertheless still supports abundant **wildlife**. Wild hogs, white-tailed deer, turkey, groundhogs, and ruffed grouse are among the species that can be seen and/or heard in the back country. Black bear have done particularly well under the protection and management of the **National Park Service**, to the extent that they have become habituated to the presence of humans and frequent rest-stops, campsites, and picnic areas. Campers, hikers, and even day trippers in vehicles need to be knowledgeable about bear behavior and about food storage and **garbage** disposal procedures which help to minimize unwanted attention from the bears.

Several species of trout are found in abundance in the cool and clear mountain streams. Estimating conservatively, about 250 species of birds may be seen in the Park at various times during the year, 165 of these species being resident. The avian population includes twenty varieties of warbler, thirty of finch, and twenty of geese and ducks. The higher elevations provide **habitat** for ravens and hawks, as well as occasional peregrine falcons and eagles.

GSM National Park also contains approximately 72 mi (116 km) of the Appalachian Trail, which runs along the crest of the Appalachians all the way from Mt. Katahdin, a granite monolith in Maine, south to Springer Mountain in Georgia. In the Park, the Appalachian Trail runs from the Pigeon River to the Little Tennessee River, and here can be found the highest, roughest, and some of the most scenic segments of the entire route. Over 900 mi (1,450 km) of other trails provide hikers and horseback riders with access to dozens of waterfalls, mountain meadows, and scenic, grassy balds.

[*Lawrence J. Biskowski*]

Green advertising and marketing

In the last decade growing consumer interest in environmental issues has significantly impacted how advertisers market their products and companies. The evidence regarding this greater concern for the environmental impact of commercial goods has been documented by several marketing groups. A 1989 survey by Michael Peters consultants found that 53% of the Americans asked had refused to buy a product in that year because of the effect of the product or package on the **environment**; 75% indicated that they would purchase a product with **biodegradable** or recyclable packaging even if it meant spending more money. In 1990 an Abt Associates study of American consumers showed that 90% of those interviewed were willing to pay more for environmentally-friendly products. For many years, German, Scandinavian, and Dutch consumers had shown a willingness to buy phosphate-free **detergents** and other so-called environmentally-friendly products. Indeed, a German business was saved from bankruptcy by offering a washing machine that consumed less water, detergent, and energy than its rivals. In England, *The Green Consumer Guide*, by John Elkington and Julia Hailes, was a best-seller for four weeks after its publication. Generally, the most environmentally-concerned consumers were well-to-do with the most discretionary income and the highest educational level. In short, they were trend-setters that advertising and marketing people could not ignore.

Marketers began to commonly use the terms "environmentally friendly," "safe for the environment," "recycled," "degradable," "biodegradable," "compostable," and "recyclable." Cause-related marketing also became popular as companies promised to support moderate environmental organizations such as **World Wildlife Fund**. While the advertising practices of many companies went uncontested by environmental groups, concerns arose regarding the claims of certain companies. For example, the Mobil Oil Corporation was sued for misleading advertising after claiming that its plastic Hefty **garbage** bags were recyclable. After suffering much embarrassment, British **Petroleum** was forced to withdraw its claim that its new brand of unleaded **gasoline** caused no **pollution**. Reacting to these and similar findings, 10 state Attorney Generals issued a report in 1990 calling for greater accountability in "green" marketing. The **Environmental Protection Agency** (EPA) and the Federal Trade

Commission also devised standards to evaluate the claims made by advertisers.

Often, the issue has been whether one product is really better for the environment than another. For instance, phosphate-free detergents created a controversy when they were introduced in France. Some companies claimed that they were no more environmentally benign than detergents that had **phosphates**. Rhone-Poulenc, the French producer of the detergents with phosphates, ran ads of dead fish apparently killed by the substances in the detergents which did not have phosphates. Proctor & Gamble launched a campaign which claimed that **disposable diapers** actually had less negative environmental impacts than reusable diapers. They pointed to the detergents, hot water, and energy used in washing cloth diapers, the energy needed to bring them to consumers, and the pesticides that were in the cotton out of which they were made.

Life-cycle assessments came into vogue as companies argued about the relative environmental merits of various products. Assessments exam the total environmental impact of using the product and how it rates—environmentally—to other similar products. Migros, the large Swiss retailer, has developed an "eco-balance" or life-cycle program to analyze the impact of its packaging in terms of the resources used and how they are disposed of.

Green labeling programs exist in Germany (**Blue Angel**), Canada (Environmental Choice), and Japan (Ecomark). They are run by the governments of these countries, but the United States government has not been willing to give this kind of endorsement to commercial products. Instead, various environmental groups have **seals** of approval which they have applied to selected goods that pass their tests of environmental acceptability. *See also* Environmentalism; Green packaging; Green products; Recycling

Green belt/greenway

A green belt is an area of land that usually surrounds a town or city, and is kept open by government restrictions on further development. Often it comprises both public and private land.

Green belts provide both recreational areas and landscape, but their main purpose is to contain cities, diverting future growth, and preventing cities and towns from merging.

It grew out of Sir Ebenezer Howard's "Garden City" approach to town planning, which aimed to provide natural areas for residents of cities. Garden cities were surrounded by countryside; city expansion was only to take place by developing new garden cities on the other side of the green belt. The result would be clusters of cities grouped around a central city. Several garden cities (e.g., Welwyn in England) were built in Britain.

In the 1920s, London's government called for study of an "agricultural belt," although the farming function was considered incidental. Its key purpose was to act as a barrier to growth. Ultimately, these were to serve as open spaces. Sir Raymond Unwin proposed a "green girdle" of spaces easily accessible to towns and cities. This plan led to the 1938 Green Belt Act, and about 38,000 acres (15,580 ha) were purchased. After World War II, green belts were again proposed as a means to limit development. A green belt about 5 mi deep (8 km) separated the inner city and the suburbs from the outer countryside. Land was both purchased and controlled through zoning compensation and by purchasing development rights. Typically, farming was allowed, but housing was not. By 1959, 840 mi^2 (2,175 km^2) had been secured. The green belt was not considered completely successful, as it did not halt London's growth, and residents' use of the lands was not high, as they were not easily accessible.

Other difficulties, according to William H. Whyte, author of *The Last Landscape,* were the time and expense of controlling land and maintaining it, arbitrary placement of the green belt areas (not following natural boundaries) and lack of function attached to the land.

Green belts today emphasize the landscape and recreational values of open areas. Containment is negative and it does not work, a conclusion the Japanese came to in 1965 when they abandoned a proposed London-type green belt to contain Tokyo.

The green belt concept came to the United States much later, and many would say that it grew into the *greenways* concept, which have the specific purpose of providing open space and recreational areas. In the United States, the term is often used interchangeably with the term greenway, although the meaning is somewhat different.

Greenways, according to Jennifer Howard, author of *Greenways: A Citizen's Guide,* are linear corridors of land and water and the natural, cultural, and recreational resources they link together. They help conserve a variety of resources and create recreational opportunities.

Greenways were inspired both by green belts and by the work of landscape architect Frederick Law Olmstead, who, in the late 1800s, designed a number of urban park

systems he called "parkways." One of his most notable is the Emerald Necklace, a string of park areas around Boston.

They may take the form of a riverfront walkway, a bicycle path, an urban walking trail connecting historic sites and neighborhood parks, a **wildlife migration** corridor, among others. Greenways are typically categorized as river greenways, paths and trails, cultural and historic greenways, wildlife corridors. They are typically comprising both public and private lands, and can include trails, riverways, **habitat** and resource **conservation** areas, notable natural features, scenic roads, historic structures, vacant urban lands, forestland, and farm fields—basically any resource that is significant to a community. Greenways help make these resources accessible to residents without need for a car. Four categories of land and **water resources** can be incorporated into a greenway system: resource-conservation areas, parks and open spaces, cultural and historic resources, and the corridors of land and water which connect these other elements together.

In the last 20 years, the greenway concept has increased in recognition and popularity. Today, hundreds are underway. In 1987, The President's Commission on Americans Outdoors focused national attention on greenways, and recommended their establishment "to link together the rural and urban spaces in the American landscape."

In Massachusetts, several greenways exist. The Connecticut River Greenway State Park in Massachusetts comprises about 3,500 acres (14,350 ha) of land owned or controlled by the Department of Environmental Management along a 70-mi (113-km) stretch of the Connecticut River. Much of the land is in private ownership and includes farms and woodlots.

The Massachusetts Bay Circuit encircles the entire Boston Metropolitan area; within Boston, the Emerald Necklace, a string of parkways, was planned by Frederick Law Olmsted. Other notable green belts exist in Portland, Oregon; Vienna; and Tokyo.

Green consumerism

see **Green advertising and marketing; Green Cross; Green products**

Green Cross

Long used by several organizations, the Green Cross has become a symbol of environmental awareness and responsibility.

A religiously oriented group officially called the American Association of the Green Cross is based in Colorado Springs, Colorado, and describes itself as "a new Christian environmental organization whose purpose is to address the ethical and moral issues underlying ecological issues, and to mobilize volunteers in service to Creation." The group's motto is "serving and keeping Creation," and it encourages such activities as "the development of every church as a Creation-awareness center, education about Christian responsibility for the earth, local action to address ecological issues." The group also promotes tree planting, urban gardening, **habitat** restoration, resource **conservation**, and **waste reduction**. It is associated with the North American Conference on Christianity and Ecology, and it plans to establish a network of chapters in churches, schools, youth groups, and colleges.

The International Green Cross and Green Crescent is a new environmental group formed in April 1993 and headed by former Soviet President Mikhail S. Gorbachev. Hoping to do for the **environment** what the Red Cross and Red Crescent have done for disaster relief, the International Green Cross will work to coordinate environmental efforts on a global scale. Mr. Gorbachev has said that he accepted leadership of the group because "I am convinced that saving the environment is the number one priority for all countries." Sponsors of the organization include an array of distinguished world political and spiritual leaders, including India's Mother Teresa and Javier Perez de Cuellar, the former Secretary General of the United Nations.

The Green Cross Certification Company is the former name of a non-profit group that awarded certifications to manufacturers whose products met certain limited environmental standards. The certification program is now administered by Scientific Certification Systems, Inc. (SCS), a private, for-profit laboratory that charges manufacturers a fee to research products and to verify their performance and claims. SCS says that it is "committed to developing programs that motivate private industry to work toward an environmentally sustainable future" by "conducting independent, unbiased evaluations of products and product claims, and recognizing products achieving exceptional environmental performance goals." The SCS Environmental Report Card summarizes the environmental performance of a product, including the amount of "environmental burden" associated with the product and its packaging.

SCS emphasizes that it does not approve products as "green" or environmentally acceptable, but rather verifies

the environmental claims that companies make for their products and analyses their environmental impact. SCS tries to evaluate a product's life cycle program, the impact it has from manufacture to disposal. Factors considered usually include the toxic waste generated and the energy used in production, the recycled content of the product, and its recyclability or biodegradability upon disposal. Different product categories have varying standards of acceptability depending on the state of technology for the above factors for the particular product or industry. *See also* Environmental consumers; Environmental ethics; Green advertising and marketing; Green products; Nongovernmental organization

[*Lewis G. Regenstein*]

Green packaging

Packaging is the largest form of domestic **garbage**. In 1999 it amounted to 33.1% of **solid waste** as measured by weight in the United States. Significant waste prevention implies reductions in packaging. There simply is not enough room in landfills or incinerators for all the excess packaging the industry produces.

People value products not only for their content but also for the packaging. It gives products a better feel and a more attractive appearance and suggests less of a risk of contamination. It prolongs the life of the product and allows people to make fewer trips to the supermarket.

For purely economic reasons most packages are becoming lighter. **Aluminum** cans, for instance, are 45% lighter today than they once were. Shrink wrap film and a plastic base are increasingly taking the place of corrugated boxes. Some companies are trying to eliminate packaging entirely. Outer boxes were once thought to be absolutely essential for the sale of toothpaste, but the giant Swiss retailer, Migros, discovered that consumers ultimately became accustomed to unboxed tubes and that sales did not suffer as a result. McDonald's and other fast food restaurants in the United States have stopped using **polystyrene** boxes to package their sandwiches, turning instead to paper wraps. Other innovations in packaging are also occurring. For instance, Procter & Gamble is no longer using metal-based inks for printing on packages. *See also* Container deposit legislation; Green advertising and marketing; Waste reduction

Green plans

Green plans are comprehensive environmental strategies that are intended to improve environmental quality and make rapid progress towards sustainability. (In its use here, the word "green" is non-political and non-ideological, and merely refers to a context of environmental protection and sustainable development.) Green plans are characterized by a longer-term view, while being thorough in their consideration and integration of environmental issues. Green plans also take account of economic realities, while consistently ensuring an appropriate degree of protection of environmental quality and natural ecological values (such as the needs of **endangered species** and rare ecosystems).

Green plans represent an extremely important tool for the longer-term protection of environmental quality, **conservation** of **natural resources** and ecological values, and achievement of a sustainable economic system. Green plans do this by proposing sustainable alternatives to the many kinds of modern activities that are causing damages to the **environment** and **biosphere**. Green plans attempt to integrate the economic, scientific, and political interests of society to develop a strategy that can achieve a sustainable prosperity for present and **future generations** of humans and their economic systems, while also supporting other **species** and natural ecosystems.

Green plans are designed to replace more conventional methods for protecting the environment. These conventional methods include the following:

(1) *Sectoral structures of government and administration.* This type of structure can be a problem because there is often a lack of integration among sectors, even though there may be important environmental linkages. For example, environmental management by government typically involves separate agencies responsible for **air pollution**, **water pollution**, forestry, agriculture, fisheries, metal resources, fossil-fuel resources, industrial development, human health, **biodiversity** (i.e., the conservation of indigenous species and ecosystems), and other environment-related mandates. Because the responsibilities of these agencies are not well integrated, they often work at cross-purposes. For instance, agencies responsible for managing harvests of timber may not take adequate consideration of the interests of agencies concerned with **pollution**, endangered species, or rare ecosystems (such as old-growth forests). This commonly results in environmental and ecological damages being caused by timber harvesting, with attendant controversies.

(2) *Single-issue policies.* Single-issue policies may result from the actions of special-interest groups, which are seeking to advance their particular environmental, ideological, or socio-economic agendas. This can, however, result in poor integration among issues, and divisive political and social

controversies that can impair the development of policies that would achieve balanced levels of environmental protection. Single-issue policies often result in regulation through short-term objectives and standards that focus on individual issues, such as the concentrations of particular **chemicals**, or the abundances of certain species. This can result in actions that focus on compliance with narrow regulatory criteria, rather than the more comprehensive, longer-term environmental goals that are pursued by green plans.

Green plans can be implemented by agencies of government at all levels (that is, federal, state or provincial, county, and city or town), and by companies of any size. Green plans can be designed by any of these organizations, but this is done in close consultation with the public, non-governmental organizations, and environmental specialists. In fact, multi-sectoral and multi-organizational discussions are one of the most important aspects of green plans. This process allows a broad degree of understanding to be reached among the spectrum of interest groups, allowing green plans to bridge political and ideological differences concerning environmental issues.

Green plans have already been implemented by the national governments of Canada, the Netherlands, New Zealand, and Singapore. Green plans are also being developed or seriously considered by the national governments of Austria, Denmark, Germany, Norway, Sweden, and the United Kingdom, and by the European Community as a whole. In addition, many state and provincial governments, municipalities, and companies in some of those countries have implemented green plans. Non-governmental environmental organizations are also advocating that green plans be designed by federal and state governments and companies in the United States. Unfortunately, significant actions in this regard have not yet been undertaken in that country. It is likely, however, that green plans will also be developed in the United States, once their benefits become more broadly recognized.

Green politics

Green Politics is a relatively recent political movement that places a concern for **nature** and its myriad **species** at the top of its agenda. New social and political movements arise in response to crises that are perceived to be both long-term and **systemic**. The crisis out of which the broadly based Green movement has emerged is the environmental crisis, which is actually a series of interconnected crises caused by **population growth**, air and **water pollution**, the destruction of the tropical and temperate rain forests, the rapid **extinction** of entire species of plants and animals, the **greenhouse effect**, **acid rain**, **ozone layer depletion**, and other now familiar instances of **environmental degradation**. Many are by-products of technological innovations, such as the internal **combustion** engine. But the causes of these environmental crises are not only technological but are also broadly cultural and political. They stem from beliefs and attitudes that place human beings above or apart from nature. Despite their differences, the major mainstream political perspectives–liberalism, socialism, and conservatism—are alike in viewing nature as either a hostile force to be conquered or a resource base to be exploited for human purposes. All, in short, share an anthropocentric, or human-centered, bias.

Against these views, the modern environmental or Green movement counterpoises its own perspective. Many **Greens** prefer not to call their perspective a political ideology, but an environmental ethic. Earlier ecological thinkers, such as **Aldo Leopold**, spoke of a "land ethic." Others, such as Christopher stone, speak of an ethic with the earth itself at its center, while still others, such as Hans Jonas, speak of an emerging "planetary ethic." Despite differences of accent and emphasis, however, all are alike in several important respects. An environmental or Ecological ethics, they say, would include several key features. First, such an ethic would emphasize the web of interconnections and mutual dependence within which we and other species live. From the this recognition of interconnectedness a second feature follows: a respect for all life, however humble humans may believe it to be, because the fate of our species is tied in with theirs. And since life requires certain conditions to sustain it, the third feature follows: we have an obligation to respect and care for the conditions that nurture and sustain life in its myriad forms. Since nature nourishes her creatures within a complex web of interconnected conditions, to damage one part of this life-sustaining web is to damage the others, and to endanger the existence of the creatures that depend upon it.

Green thinkers hold that the enormous power that humans have over nature imposes on our species a special responsibility for restraining our reach and using our power wisely and well. Greens point out that the fate of the earth and all its creatures now depends, to an unprecedented degree, on human decisions and actions. For not only do we depend on nature, but nature depends on our care and re-

straint and forbearance. Humans have the nuclear means to destroy in mere minutes the earth's inhabitants and the ecosystems that sustain them. From this emerges a fourth feature of a "green" political perspective: Greens must oppose militarism and work for peace.

But the earth is in danger not only from global thermonuclear war but from the slower destruction of the natural **environment**. Such destruction is a consequence not only of large-scale policies but of small-scale, everyday acts. And each of us bears full responsibility for our actions and also, since we live in a democracy, some share of responsibility for cumulative effects and collective outcomes. Each of us has, or can have, a hand in making the laws under which we live. It is for this reason that Greens give equal emphasis to our collective and individual responsibility for protecting the environment that protects us. The fifth feature of the Green political perspective, then, is to emphasize the importance of informed and active democratic citizenship at the grass-roots level. Hence the Green adage, "Think globally and act locally."

On this much most Greens agree. But there are also a number of unresolved differences of approach, emphasis, and political strategy. The internal ideological spectrum ranges from "light green" conservationists to "dark green" radicals, and includes assorted anarchist beliefs, **deep ecology**, **ecofeminism**, **social ecology**, **bioregionalism**, New Age Gaia worship, and other groupings, each differing in various ways form the others. Among these are differences regarding the basic beliefs underlying and motivating the green movement. Some New Age Greens envision an environmental ethic grounded in spiritual or religious values. We should, they say, look upon the earth as a benevolent and kindly deity—the goddess *Gaia* (from the Greek word for "earth")—to be worshiped in reverence and awe. In this way we can liberate ourselves from the restrictive rationalism that characterizes modern science. Other Greens disapprove of such a spiritual or religious orientation, contending that such beliefs are politically pernicious and inimical to the rational scientific thinking required to diagnose and solve environmental problems.

Other differences have to do with the political strategies and tactics to be employed by the environmental movement. Some say that Greens should take an active part in electoral politics, perhaps even following the lead of Greens in Germany and organizing a Green Party. Aware of the formidable obstacles facing minority third parties, most have favored other strategies, such as working within existing mainstream parties (especially the Democratic Party in the United States), or hiring lobbyists to influence legislation. Still other Greens favor working outside of traditional interest group politics, believing the earth and its inhabitants hardly constitute a special interest. Others, such as social ecologists, tend to favor local, grass-roots campaigns which involve neighbors, friends, and fellow citizens in efforts to protect the environment. Some social ecologists are anarchists who see the state and its pro-business and pro-growth policies as the problem, rather than the solution, and seek its eventual replacement by a decentralized system of communes and cooperatives. Greens of the "bioregionalist" persuasion add that such social and political organization ought to be based on biological or natural, rather than artificial or political, boundaries and regions.

Although all Greens agree on the importance of informing and educating the public, they disagree as to how this might best be done. Some groups, such as **Greenpeace**, favor dramatic direct action calculated to make headlines and capture public attention. Even more militant groups, such as the Sea Shepherd Society and **Earth First!**, have advocated **monkey-wrenching** as a morally justifiable means of publicizing and protesting practices destructive of the natural environment.

Such militant tactics are decried by moderate or mainstream groups, which tend to favor subtle, low-key efforts to influence legislation and inform the public on environmental matters. The **Sierra Club**, for example, lobbies Congress and state legislatures to pass environmental legislation. It also publishes books and produces films and videos about a wide variety of environmental issues. Similar strategies are followed by other groups, such as the **Environmental Defense** Fund. Another group, **The Nature Conservancy**, solicits funds to buy land for nature preserves.

Differences over strategy and tactics are, however, differences about means and not necessarily about basic assumptions and ends. Despite their political differences, Greens are alike in assuming that all things are connected—ecology is, after all, the study of interconnections—and they agree that complex ecosystems and the myriad life-forms they sustain are valuable and worthy of protection by political and other means. *See also* Abbey, Edward; Bioregional Project; Bookchin, Murray; Brower, David Ross; Environmental attitudes/values; Environmental Defense Fund; Foreman, Dave; Green advertising and marketing; Green products; Sea Shepherd Society; Sierra Club

Green products

Some companies have thrived by marketing product lines as environmentally correct or "green." A prime example is Body Shop, a cosmetics company that is strongly and explicitly pro-environment with regard to its products. It strives, for instance, to develop products made with substances derived from threatened tropical rain forests so that they can be preserved.

The American ice cream manufacturer, Ben and Jerry's, has adopted a similar approach to using **rain forest** products in what it sells. Mercury- and cadmium-free batteries have been marketed by Varta, a German company. Ecover, a small Belgian company, made major sales gains when it began to market a line of phosphate-free **detergents**. Wal-Mart is another company that provides its customers with green products. Loblaw, a Canadian grocery chain, has introduced a "green-line" of environmentally-friendly products and has sold more than twice the amount than it had initially projected. Seventh Generation, a mail-order company based in California, has successfully marketed its own line of recycled toilet paper, **biodegradable** soaps and cleansers, and phosphate-free laundry and dishwashing detergent.

Many factors comprise a green product. The product has to be made with the fewest raw materials and produced with the least amount of contaminants released into the **environment** and with the smallest effect on human health.

Consideration must also be given to how consumers will use the product and how they will dispose of it when they are finished. To reduce its waste potential, a product must often last a significant amount of time or be reusable or recyclable.

As consumers become more aware of environmental issues, they will likely look to producers and governments to provide more products that will permit them to maintain a life-style that is less harmful to the environment. Therefore, the very nature of products will have to change. They will have to be lighter, smaller, and more durable so that they can consume fewer resources in their production and use and take up less space when they are disposed of.

Ultimately, a real revolution in the use of green products would mean replacing or substantially modifying virtually the capital stock of society—appliances, automobiles, housing, highways, etc.—with a different type of product. In contrast to old smokestack industries, new technologies and emerging industries—such as telecommunications, computers, and information—should be able to offer products that are less environmentally harmful. They should be able to produce many new types of green products and modify existing products so that they are less damaging to the environment.

Green Seal

An independent, non-profit group that encourages the production and sale of consumer products that are environmentally responsible, Green Seal allows the use of its certification mark on products that meet its strict environmental standards. The mark has a green check over a blue globe.

A growing number of people are becoming aware that consumer demand for certain products causes great harm to the **environment** and provides an economic incentive for activities that damage the planet. Some examples are products that contain **chemicals** such as **chlorofluorocarbons** (CFCs), which deplete the earth's protective **ozone** layer; mahogany and other kinds of wood from rapidly-disappearing tropical rain forests; fur coats made from rare and **endangered species**; tuna caught using techniques that kill **dolphins**; and products that waste energy or water, are overpackaged, cannot be recycled, or are harmful when disposed of.

Green Seal symbol. (Photograph by Tom Pantages. Reproduced by permission.)

By avoiding these products and buying those that do not cause harm to **wildlife** or degrade the environment, consumers can encourage corporations to make and sell goods that are environmentally responsible. With the public's growing commitment to protecting the environment, store shelves are now full of products that claim to be earth friendly, environmentally friendly, recycled, **biodegradable**, natural, organic, or are labeled in such a way as to take advantage of **green advertising and marketing**.

The Green Seal certification mark helps consumers choose those products that actually are less harmful to the planet and are not simply marketed in a clever way. Green Seal uses the highly respected Underwriters Laboratory (UL) for most of its product testing and certification. Through its certification process and its educational activities, Green Seal encourages people to think about how they can help protect the environment in their everyday activities and their daily lives.

Green Seal points out that its research shows that four out of five consumers are more likely to buy a product with its certification mark when choosing between similar products. A Gallup survey found that the Green Seal certification would have more impact on consumers than would government guidelines. Thus, consumers, guided by Green Seal, have the opportunity to influence the actions of major corporations and their impact on the environment through their purchasing decisions.

Green Seal is headed by Arthur B. Weissman, who serves as its President and Chief Executive Officer. Its Chairman of the Board is Denis Hayes, the well-known environmentalist and **solar energy** advocate who organized the 1970 and 1990 **Earth Day** celebrations.

Green taxes

The search for alternatives to legislation and enforcement of **environmental policy** led a 1988 bipartisan Congressional study group (Project 88) to call for the use of market forces, including taxes, to protect the **environment**. Project 88's advocacy of these "green" taxes and other economic incentives for reducing **pollution** is actually an old idea. Charles Schultze, chairman of the Council of Economic Advisers under President Jimmy Carter, maintained in the 1976 Godkin Lectures delivered at Harvard University (later published as a book titled *The Public Use of the Private Interest*) that detailed laws and bureaucratic requirements were a costly and ineffective way to control pollution. Instead, reliance should be placed on taxes and subsidies that would make private interests more congruent with public goals.

The economists' argument, posed by Project 88, Schultze, and others, is that the harm pollution causes to health, property, and aesthetics is not paid for by business. Industries have no reason to consider this harm in their production decisions. By taxing pollution, the government would make polluters pay for the damage they inflict. External production costs would be incorporated into ordinary production decisions. This would correct a market defect and the market would become more efficient. Green taxes would not lower environmental standards; they would provide more protection at the same level of expenditure, or the same protection with less money.

The present regulatory system is expensive and inefficient. The amount of litigation is excessive, and relations between business and government suffer. The uniform standards often do not make sense, because different companies have different removal costs depending on their production process and other factors. For example, a study in the St. Louis area found that removing a ton of **particulate** matter

from a paper factory cost $4, while removing the same material from a brewery cost $600.

Industries that can easily reduce pollution should be encouraged to go beyond the standard and not stop at mere compliance. Businesses for whom pollution reduction is a great burden should be able to pay a fine equivalent to the damage caused. To impose the same requirements on all businesses regardless of cost is unfair. Moreover, regulations do not permit pollution-reducing experiments. Companies should be allowed to choose the lowest-cost method whether it means treating wastes, modifying production processes, substituting less-polluting raw materials, or other innovations. By shifting away from uniform standards, pollution-control costs can be cut drastically. According to one study, an equivalent **air quality** can be achieved at 10 percent of existing costs.

Why have governments been so slow to implement green taxes? The primary reason is because taxes have never been popular with legislators or their constituents. Nor do interest groups support them. Businesses prefer court delays and lobbyists, to the certainty of taxes. Environmentalists argue that pollution must be eliminated and that companies should not be given the right to pollute for a fee. Bureaucrats, moreover, have been comfortable with the existing system. Pollution-tax proposals proposed by Presidents Lyndon Johnson and Richard Nixon were almost immediately dismissed.

During the Clinton administration there was new interest and support for pollution tax proposals. However, the necessary Congressional support did not materialize. Moreover, industry spokespersons and lobbyists promoted the idea that definitive scientific proof for global warming had yet to be established.

However, in 2002, during the Bush administration, which had previously stated that there was not enough evidence to link industrial emissions to global warming, the **Environmental Protection Agency** released a report that endorsed what many scientists had argued, i.e., that oil refinery, **power plants**, and auto emissions were important causes of global warming. In 2001, President Bush had caused international outrage when he said that he would not join other nations in ratifying the Kyoto Protocol, a United Nations plan to cut emissions of green house gases, because he claimed it would be too costly to the American economy.

Yet by 2002 at least nine European nations had implemented environmental taxes as a means of reducing air pollutants, the growing shortage of **landfill** space, and to promote the **conservation** of water and electricity. But in spite of the growing concern over global warming and pollution, efforts to implement environmental taxes have not found the needed support in this country due in large part to a general anti-tax sentiment. At this point there still remains a majority interest in preserving the status quo as opposed to addressing needed environmental concerns through such measures as environmental tax reform. With the growing body of evidence supporting the need for action, and pressure from other nations, that sentiment may change in the future. However, the issue at that time will more likely be whether or not it is too little reform, too late. *See also* Corporate Average Fuel Efficiency Standards; Environmental economics; Externality; Internalizing costs; Pollution control; Pollution control costs and benefits

Greenhouse effect

The greenhouse effect is a natural phenomenon that traps radiation within the earth's **atmosphere**. Natural **greenhouse gases** include water vapor, **carbon dioxide**, **nitrous oxide**, **methane**, and **ozone**, all essential to support life. The enhanced greenhouse effect, the direct result of human activities, increases concentrations of these gases in the atmosphere, and leads to **pollution** of the lower atmosphere and contributes to global warming. These gases let in sunlight but tend to insulate Earth against the loss of heat, as do the glass walls of a greenhouse. A higher concentration of the greenhouse gases means a warmer **climate**. For example, the twentieth century was been 1° warmer on worldwide average than the nineteenth century—warming at a rate 20 times faster than average.

Carbon dioxide (CO_2) is considered the predominant greenhouse gas and has the greatest impact on global heat. From April 1958, when monthly measurements of CO_2 from atop the Mauna Loa **volcano** began, through June 1991, the CO_2 concentration in **parts per million** went from 316 ppm to almost 360 ppm. The peak concentration is due to the destruction of tropical rain forests and the burning of **fossil fuels**, which accounts for half of the greenhouse gases added to the atmosphere. CO_2 is dumped into

the atmosphere at a much faster rate than it can be withdrawn or absorbed by the oceans or living things in the **biosphere**; since 1765, its presence in the atmosphere has increased by over 27%. CO_2 buildup in the next few decades to centuries could be one of the principal controlling factors of the near-future climate.

Methane, another greenhouse gas, is produced when oxygen is not freely available and bacteria have access to organic matter, such as in swamps, bogs, rice paddies and moist soils. Methane also is produced in the guts of termites and cows, in **garbage** dumps, landfills, emissions from **coal** mining, **natural gas** production and distribution, and changing **land use**. Methane concentrations have increased over 100% since 1765.

Nitrous oxide concentrations have increased in recent years due to **fertilizer** use and chemical production, such as in the manufacture of nylon. Nitrous oxide is also dispersed during fossil fuel **combustion**, **biomass** burning and changing land use.

CFCs (**chlorofluorocarbons**), also implicated in **ozone layer depletion**, act as greenhouse gases. While useful and widely used as refrigerants, their total effect is significant because compared to a molecule of carbon dioxide, each molecule of CFC absorbs much more radiation, thereby **trapping** heat in the atmosphere.

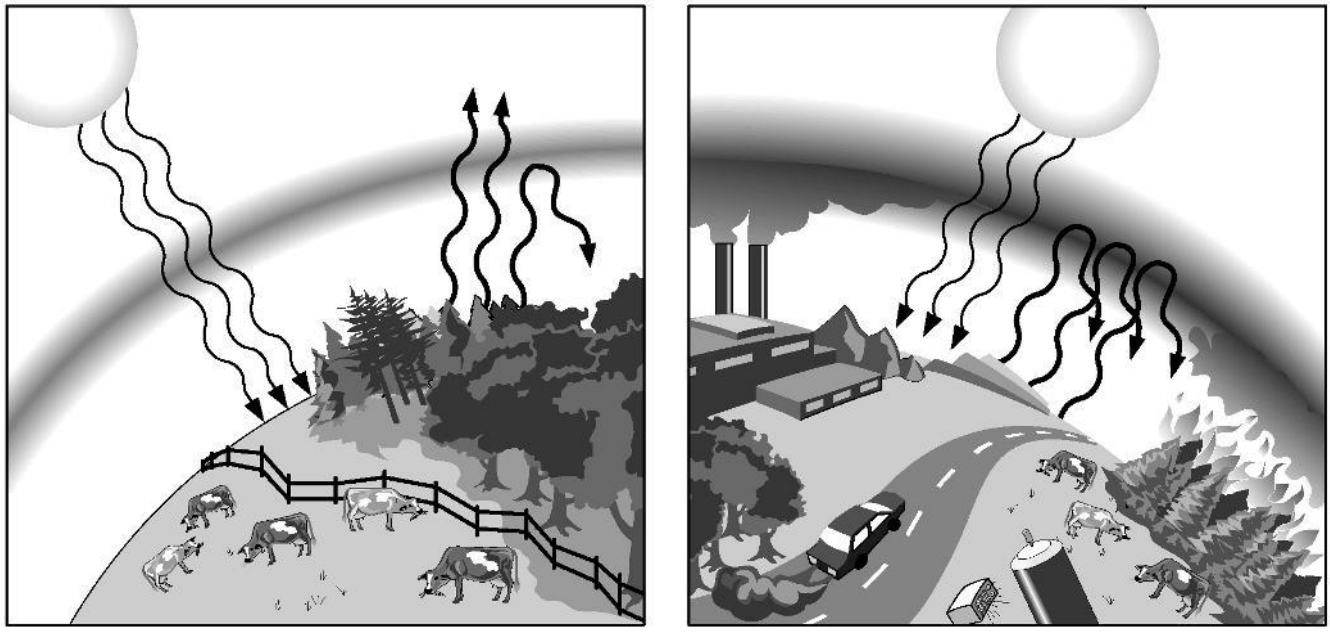
Other greenhouse gases are ground-level ozone (sunlight reacting with **automobile emissions**). and water vapor. Water vapor represents about two% of total atmospheric composition, and is the most abundant greenhouse gas. With methane and carbon dioxide, it plays an important role in regulating the temperature of the planet through the production of clouds.

Rain forest destruction also contributes to global warming. When the canopy of leaves is removed through **clear-cutting** or burning, the sudden warming of the forest floor releases methane and CO_2, in a kind of biochemical burning. The massive increase in the number of dead tree trunks and branches leads to a population explosion of termites, which themselves produce methane. Dead trees can no longer store CO_2 or convert it to oxygen.

Two factors which appear to mitigate the effect of enhanced greenhouse gases are aerosols and dust. Aerosols, minute solid particles, are finely dispersed in the atmosphere and have become an influence on the greenhouse effect. Aerosols are produced by combustion, but they also come from natural sources, primarily volcanoes. By blocking light, aerosols and dust can offset warming from greenhouse gasses. For example, a significant cooling trend in the spring and summer of 1992 seemed to correlate with the eruption of **Mount Pinatubo** in the Philippines. The fall and winter of 1992 were fairly mild on worldwide average. As all the **particulate** matter from the Mt. Pinatubo eruption settled out of the atmosphere, the surface cooling effects abated and the global warming trend resumed.

Anthropogenic (human-caused) greenhouse gases now appear responsible for increasing the global average temperature. According to current projections, global temperatures may rise as much as 35.6–37.4° F (2–3° C) above the pre-industrial temperatures by the year 2100. To place this change in perspective, the temperature rise that brought the planet out of the most recent **ice age** was only about 37.4–39.2° F (3–4° C).

The top 10 warmest years of average global recorded temperatures were in the last 15 years of the twentieth centry and saw devastating fires in **Yellowstone National Park**, **flooding** in Bangladesh, record number of hurricanes and tornados, and a deadly heat wave and **drought** in the southeastern United States. It is probable, based on computer models, that a resumption in warming will accompany changes in regional weather. A 40-year trend of increased precipitation in Europe and decreased precipitation in the African **Sahel** (Ethiopia, the Sudan, Somalia) may be an early consequence of global warming due to the greenhouse effect. Longer and more frequent heat waves would result in public health threats as well as inconveniences such as road buckling, electrical brownouts, or blackouts.



Precipitation is likely to increase regionally because as the temperature increases, more evaporation takes place, leading to more precipitation. The average precipitation event is likely to be heavier: wetter monsoons in coastal subtropics; more frequent and heavier winter snows at high altitudes and high latitudes; an earlier snowmelt, and a wetter spring.

Increases in rain- or snowfall are not expected to offset the effects of higher temperatures on **soil**, however. Higher temperatures are expected to dry the soil in North America and southern Europe, among other places, by boosting the rates of evaporation and **transpiration** through plants. More favorable agricultural conditions in high latitudes could move the center of agriculture farther north into Canada and Siberia and out of the United States.

Other consequences of global warming from the enhanced greenhouse effect include the reduction of sea ice, coastal sea level rises of several feet per century, more frequent and powerful hurricanes, and more frequent and severe forest fires. In the United States, the frequency of tornadoes is near or above record levels for the years 1990–1994.

The rise of sea level is the most easily predicted consequence. The one-degree increase in temperature over the past century contributed to a 4–-in (10–20-cm) rise in mean sea level. This could lead to severe and frequent storm damage, flooding and disappearance of **wetlands** and lowlands, coastal **erosion**, loss of beaches and low islands, **wildlife** extinctions, and increased **salinity** of rivers, bays and aqui-

The greenhouse effect. (Illustration by Hans & Cassidy.)

fers. However, because the global atmosphere operates as a complex system, it is difficult, even with today's sophisticated computer models, to predict the exact nature of the changes we are likely to cause with increased greenhouse gases. Scientists have predicted that low-lying areas and islands, including the Seychelles, the Maldives, the Marshall Islands, and large areas of Bangladesh, Egypt, Florida, Louisiana, and North Carolina will disappear over the next few decades.

The earth's natural atmospheric cleanser — rain — may wash excess greenhouse gases out of the atmosphere. But until rates of greenhouse gases slow their rapid increases or actually begin to decrease, the planet will get warmer. In response to climate projections, the United Nations Framework Convention on Climate Change (UNFCC), adopted and signed by 162 countries in 1992 at the Rio Earth Summit, sets country-by-country standards to reduce the emissions of greenhouse gases, particularly carbon dioxide.

Policy-makers in the United States, including Vice President Albert Gore Jr., propose stricter requirements for more fuel-efficient cars, "environment taxes" that penalize heavy polluters and help pay for cleansing the atmosphere, and trading technological advances for rain forest protection in **Third World** countries. However, because global warming often is made a political ping-pong ball, changes in political administrations worldwide can extend to policy makers and climate researchers, who depend on government assistance for research.

The greatest controversy over slowing the rate of greenhouse gases injected into the atmosphere seems to be how to do it. Some scientists advocate increased use of **nuclear power** to reduce dependence on fossil fuels, but that carries its own controversies. Nuclear **power plants** are so energy-intensive just to build, the trade-off is negligible. **Conservation** and a switch from a dependence on fossil fuels to dependence on renewable resources such as wind and **solar energy**, slows the rate of increase of carbon dioxide emissions into the atmosphere. *See also* Environmental economics; Environmental policy; Global Tomorrow Coalition; *The Global 2000 Report*

Greenhouse gases

Greenhouse gases are gases in the **atmosphere** that absorb and re-emit energy from the sun. They are believed to cause the global climatic changes known as the **greenhouse effect**.

The earth's **climate** depends on a wide variety of gases, vapors, and aerosols, and many of these contribute to global warming. **Carbon dioxide** is the most abundant; the atmosphere contains about 700 billion tons of this gas, and the oceans contain about 50 times this amount. Water vapor also contributes to global warming, and other important greenhouse gases include **ozone**, **methane**, **nitrous oxide**, and **chlorofluorocarbons**. Halogenated gases and a variety of volatile organic **hydrocarbons** are also important trace gases. Volatile compounds can absorb solar and infrared radiation directly; they can also affect the photochemistry of ozone, increasing the transmission of heat and thus indirectly affecting the climate. While not gases, small long-lived ambient particles, such as particulates, agricultural fields, **wetlands**, and oceans. Industrial emissions of greenhouses gases consist largely of **carbon** dioxide; these arise from burning **fossil fuels** such as **coal**, oil, and **natural gas**.

Increases in the concentrations of carbon dioxide and methane in the atmosphere during this century have been attributed in part to rapid increases in the utilization of fossil fuels. Efforts to reduce greenhouse gases have focused on limiting and controlling the burning of these fuels. There have been programs to encourage the utilization of other sources of energy such as **nuclear power**, or **alternative energy sources** such as **solar energy** or hydropower. Technologies for controlling fossil fuel emissions and sequestering ambient carbon dioxide have also been developed, and researchers have emphasized the importance of improving **energy efficiency** and **energy conservation**. *See also* Air pollution; Air pollution control; Flue gas; Pollution control

Greenpeace

Founded in 1971, Greenpeace is an international environmental organization dedicated to protecting the global **environment** through non-violent direct action, public education, and legislative lobbying. With a worldwide membership of over 2.5 million (approximately 250,000 in Greenpeace USA), Greenpeace operates offices in some 30 countries and maintains a scientific base in **Antarctica**.

Having mounted successful campaigns on a wide variety of environmental issues, Greenpeace is perhaps best known for its direct and often confrontational crusades against nuclear testing and commercial **whaling**. The group has also garnered wide publicity for protesting various environmental abuses by hanging enormous banners from smokestacks, buildings, bridges, and the scaffolding used in the renovation of the Statue of Liberty.

Greenpeace is presently active in four broadly defined environmental issue areas—Atmosphere and Energy; Ocean Ecology and Forests; **Toxins**; and Disarmament. In the area of **Atmosphere** and Energy, Greenpeace works to eliminate widespread dependence upon **fossil fuels** and lobbies for laws and policies encouraging **energy efficiency** and **renewable energy** sources. The group is also working to

halt the spread of **nuclear power** and the dumping of **radioactive waste** as well as to ban ozone-depleting **chemicals** such as **chlorofluorocarbons** (CFCs).

With regard to Ocean Ecology and Forests, Greenpeace seeks to protect both habitats and threatened **species**, including **whales**, harp **seals**, **dolphins**, **sea turtles**, **elephants**, and birds of prey. It works to discourage **overfishing** and other wasteful fishing practices, particularly the killing of dolphins in tuna nets. Greenpeace was instrumental in protecting Antarctica by persuading 23 nations to sign an accord banning all mining in Antarctica for at least 50 years. Supporting the principle of **biodiversity**, the group also works to protect tropical and temperate forests around the world. In 2002, the ships *MV Esperanza* and *Rainbow Warrior* stopped illegally logged timber from Africa and the Amazon from being imported.

In the area of Toxins, Greenpeace is especially concerned with stopping the use of unneeded **chlorine** in the bleaching of paper and with preventing the dumping of **hazardous waste** in **Third World** nations. Particularly concerned in recent years with **dioxin**, polychlorinated biphenyl (PCB), CFCs, and pesticides, the group regularly investigates, publicizes, and lobbies against chemical **pollution**. Greenpeace also conducts research on the effects of toxic substances on human beings and the environment and encourages **recycling** as a means of reducing pollution. In 1998, Greenpeace activists prevented a PVC plant from opening in Convent, Louisiana.

Also concerned with Disarmament issues, Greenpeace conducts research into the effects of warfare on human beings and the environment and advocates the global elimination of **nuclear weapons**. More immediately, the group also urges the cessation of all nuclear and chemical weapons testing and is trying to persuade the major powers to agree to a global ban on naval nuclear propulsion.

In an effort to avoid compromising its goals and activities, Greenpeace does not seek corporate or government funding. Nor does it become directly involved in the electoral process in any of the nations in which it is active. Greenpeace's frequently confrontational tactics have on occasion provoked angry responses from various governmental authorities, including the bombing and sinking of Greenpeace's flagship vessel *Rainbow Warrior* by agents of the French government in 1985. The *Rainbow Warrior* had been in New Zealand preparing to protest French nuclear testing in the South Pacific when it was sabotaged. In October 1992 one of Greenpeace's ships was seized by the Russian coast guard while investigating Russian nuclear waste dumping in Arctic waters.

Greens

The name given to those who engage in **green politics**. The term originated in Germany, where members of the environmentally-oriented Green Party were quickly dubbed *die Grünen*, or "the Greens." In the United States, greens refers not to a particular political party, but to any individual or group making environmental issues the central focus and main political concern. Thus the term covers a wide array of political perspectives and organizations, ranging from moderate or mainstream "light green" groups such as the **Sierra Club** and **Greenpeace** to more militant or "dark green" movements and direct-action organizations such as the **Sea Shepherd Conservation Society** and **Earth First!**, as well as ecofeminists, bioregionalists, social ecologists, and deep ecologists. Greens in the United States are divided over many issues. Some, for example, are in favor of organizing as interest groups to lobby for environmental legislation, while others reject politics in favor of a more spiritual orientation. Some greens (for example, social ecologists and ecofeminists) see their cause as connected to questions of social justice—the elimination of exploitation, militarism, racism, sexism, and so on—while others (deep ecologists, for instance) seek to separate their cause from such humanistic concerns, favoring a biocentric instead of an anthropocentric orientation. Despite such differences, however, all greens agree that the preservation and protection of the natural **environment** is a top priority and a precondition for every other human endeavor. *See also* Environmental ethics; Environmentalism

Jacques Grinevald

French university professor

Jacques Grinevald is recognized as a key expert on **biospheres** His studies and publications regarding the concept's initiator, **Vladimir Vernadsky** who published his work on the subject first in 1926, have comprised the substance of Grinevald's work as a scientific historian and philosopher.

Grinevald has been on the faculty of the University of Geneva (Switzerland) since 1987, serving as a part-time lecturer. He received a science degree in policies from the University Institute of High International Studies in Geneva in 1970; and his doctorate of 3rd cycle of philosophy, Paris X-Nanterre, in 1979. His early career included positions at the University of Geneva as an assistant in charge of research

and teaching to the faculty of law, in addition to duties as the person in charge of press information; part-time lecturer position at the federal polytechnic school of Lausanne, serving as program man technique **environment** beginning in 1981; and, serving as an invited professor at the Federal Universidade of Rio de Janeiro (Brazil) in 1980 and 1984. His active schedule has taken him all over the world for conferences and seminars. Grinevald retains membership in several professional societies, including International Society for Ecological Economics; European Association for Bioeconomic Studies; and, World Council for the **Biosphere**.

Grinevald has been published extensively. His writings—among them chapters and articles in various books and journals—include, *The Greening of Europe* in 1990; "The Revolution Carnotienne: thermodynamics, economy and ideology," from the *European Review of Social Sciences*, 1976; and, "There is holistic total concept for deep and **ecology**: the Biosphere," for *Fundamenta Scientiae*, 1987. He has lectured and written on subjects that include the biosphere, the **greenhouse effect**, and famous scientists such as Stephen H. Schneider, a native New Yorker, whose research has focused on the greenhouse effect on civilization. He has been a regular contributor to a journal established by a group at the University of Geneva in 1990, *Strategies Energetiques Biosphere et Society* (Energy Strategies, Biosphere and Company) (SEBES). What began as a special volume became a publication devoted to the biosphere.

Writing for the publication *Etat De La Planete* (State of the Planet), Grinevald discussed the key issues of the biosphere. "This concept underlines the fac that the Life exceeds the individuals and is an ecological phenomenon of solidarity on various scales, microbial communities on a planetary scale of the **Biosphere**. It is the observer which decides scale of observation, so much [more] at the geographical level than at the temporal level. It is our world civilization which discovers the Biosphere as a phenomenon characteristic of the face of the Earth in cosmos. That implies a certain responsibility. The interdisciplinary and holistic concept of Biosphere associates astronomy, geophysics, **meteorology**, **biogeography**, evolutionary biology, geology, the geochemistry and, in fact, all science of the ground and the living."

Grizzly bear

The grizzly bear (*Ursus arctos*), a member of the family Ursidae, is the most widely distributed of all bear **species**. Although reduced from prehistoric times, its range today extends from Scandinavia to eastern Siberia, Syria to the Himalayan Mountains, and, in North America, from Alaska and northwest Canada into the northwestern portion of the lower 48 states. Even though the Russian, Alaskan, and Canadian populations remain fairly large, the grizzly bear population in the northwestern continental United States represents only about 1% of its former size of less than 200 years ago. Grizzly bears occupy a variety of habitats, but in North America they seem to prefer open areas including **tundra**, meadows, and coastlines. Before the arrival of Europeans on the continent, grizzlies were common on the Great Plains. Now they are found primarily in **wilderness** forests with open areas of moist meadows or **grasslands**.

Female grizzly bears vary in size from 200–450 lb (91–204 kg), whereas the much larger males can weigh up to 800 lb (363 kg). The largest individuals—from the coast of southern Alaska—weigh up to 1,720 lb (780 kg). Grizzly bears measure from 6.5–9 ft (2–2.75 m) tall when standing erect. To maintain these tremendous body sizes, grizzly bears must eat large amounts of food daily. They are omnivorous and are highly selective feeders. During the six or seven months spent outside their den, grizzly bears will consume up to 35 lb (16 kg) of food, chiefly vegetation, per day. They are particularly fond of tender, succulent vegetation, tubers, and berries, but also supplement their diet with insect grubs, small rodents, carrion, **salmon**, trout, young deer, and livestock, when the opportunity presents itself. In Alaska, along the McNeil River in particular, when the salmon are migrating upstream to spawn in July and August, it is not unusual to see congregations of dozens of grizzly bears, along the riverbank or in the river, catching and eating these large fish.

Grizzly bears breed during May or June, but implantation of the fertilized egg is delayed until late fall when the female retreats to her den in a self-made or natural cave, or a hollow tree. Two or three young are born in January,

A grizzly bear (*Ursus arctos*). (Reproduced by permission.)

February, or March, and are small (less than 1 lb/0.45 kg) and helpless. They remain in the den for three or four months before emerging, and stay with their mother for one and a half to four years. The age at which a female first reproduces, litter size, and years between litters are determined by nutrition, which induces females to establish foraging territories which exclude other females. These territories range from 10–75 mi^2 (26–194 km^2). Males tend to have larger ranges extending up to 400 mi^2 (1,036 km^2) and incorporate the territories of several females. Young females, however, often stay within the range of their mother for some time after leaving her care, and one case was reported of three generations of female grizzly bears living within the same range.

Grizzly bear populations have been decimated over much of their original range. **Habitat** destruction and **hunting** are the primary factors involved in their decline. The North American population, particularly in the lower 48 states, has been extremely hard hit. Grizzly bears numbered near 100,000 in the lower 48 states as little as 180 years ago, but, today, fewer than 1,000 remain on less than 2% of their original range. This population has been further fragmented into seven small, isolated populations in Washington, Idaho, Montana, Wyoming, and Colorado. This decline and fragmentation makes their potential for survival tenuous. The U. S. **Fish and Wildlife Service** considers the grizzly bear to be threatened in the lower 48 states.

Little has been done to protect this declining species in the lower 48 states. In 1999 it was agreed to begin slowly reintroducing grizzlies into the 1.2 million acre (49,000 ha) area of the Selway-Bitterroot Wilderness on the border of Idaho and Montana. Unfortunately, the project was put on hold as of 2001 due to unfounded fear of the animal. Habitat loss due to timbering, road building, and development in this region is still a major problem and will continue to impact these threatened populations of bears.

Groundwater

Groundwater occupies the void space in a geological strata. It is one element in the continuous process of moisture circulation on Earth, termed the **hydrologic cycle**.

Almost all groundwater originates as surface water. Some portion of rain hitting the earth runs off into streams and lakes, and another portion soaks into the **soil**, where it is available for use by plants and subject to evaporation back into the **atmosphere**. The third portion soaks below the root zone and continues moving downward until it enters the groundwater. Precipitation is the major source of groundwater. Other sources include the movement of water from lakes or streams and contributions from such activities as excess **irrigation** and **seepage** from canals. Water has also been purposely applied to increase the available supply of groundwater. Water-bearing formations called aquifers act as reservoirs for storage and conduits for transmission back to the surface.

The occurrence of groundwater is usually discussed by distinguishing between a **zone of saturation** and a zone of **aeration**. In the zone of saturation the pores are entirely filled with water, while the zone of aeration has pores that are at least partially filled by air. Suspended water does occur in this zone. This water is called vadose, and the zone of aeration is also known as the **vadose zone**. In the zone of aeration, water moves downward due to gravity, but in the zone of saturation it moves in a direction determined by the relative heights of water at different locations.

Water that occurs in the zone of saturation is termed groundwater. This zone can be thought of as a natural storage area of **reservoir** whose capacity is the total volume of the pores of openings in rocks.

An important exception to the distinction between these zones is the presence of ancient sea water in some sedimentary formations. The pore spaces of materials that have accumulated on an ocean floor, which has then been raised through later geological processes, can sometimes contain salt water. This is called connate water.

Formations or strata within the saturated zone from which water can be obtained are called aquifers. Aquifers must yield water through **wells** or springs at a rate that can serve as a practical source of water supply. To be considered an **aquifer** the geological formation must contain pores or open spaces filled with water, and the openings must be large enough to permit water to move through them at a measurable rate. Both the size of pores and the total pore volume depends on the type of material. Individual pores in fine-grained materials such as clay, for example, can be extremely small, but the total volume is large. Conversely, in coarse material such as sand, individual pores may be quite large but total volume is less. The rate of movement from fine-grained materials, such as clay, will be slow due to the small pore size, and it may not yield sufficient water to wells to be considered an aquifer. However, the sand is considered an aquifer even though they yield a smaller volume of water because, they will yield water to a well.

The **water table** is not stationary but moves up or down depending on surface condition such as excess precipitation, **drought**, or heavy use. Formations where the top of the saturated zone or water table define the upper limit of the aquifer are called unconfined aquifers. The hydraulic pressure at any level with an aquifer is equal to the depth from the water table, and there is a type known as a water-table aquifer, where a well drilled produces a static water level which stands at the same level as the water table.

A local zone of saturation occurring in an aerated zone separated from the main water table is called a perched water table. These most often occur when there is an impervious strata or significant particle-size change in the zone of aeration which causes the water to accumulate. A confined aquifer is found between impermeable layers. Because of the confining upper layer, the water in the aquifer exists within the pores at pressures greater than the atmosphere. This is termed an artesian condition and gives rise to an **artesian well**.

Groundwater has always been an important resource, and it will become more so in the future as the need for good quality water increases due to urbanization and agricultural production. It has recently been estimated that 50% of the drinking water in the United States comes from groundwater; 75% of the nation's cities obtain all or part of their supplies from groundwater, and rural areas are 95% dependent upon it. For these reasons, it is widely believed that every precaution should be taken to protect groundwater purity. Once contaminated, groundwater is difficult, expensive, and sometimes impossible to clean up. The most prevalent sources of contamination are waste disposal, the storage, **transportation** and handling of commercial materials, mining operations, and nonpoint sources such as agricultural activities. *See also* Agricultural pollution; Aquifer restoration; Contaminated soil; Drinking water supply; Safe Drinking Water Act; Water quality; Water table draw-down

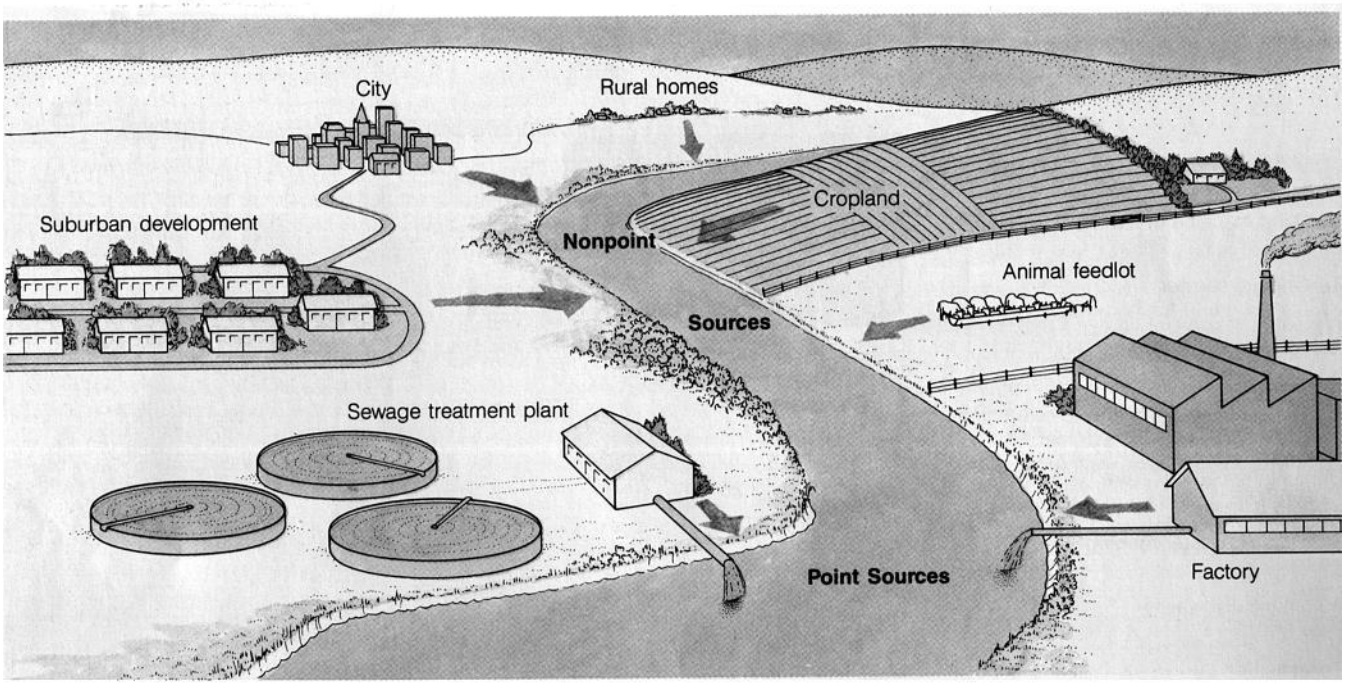
Groundwater monitoring

Monitoring **groundwater** quality and **aquifer** conditions can detect contamination before it becomes a problem. The appropriate type of monitoring and the design of the system depends upon **hydrology**, **pollution** sources, and the population density and **climate** of the region. There are four basic types of groundwater monitoring systems: ambient monitoring, source monitoring, enforcement monitoring, and research monitoring.

Ambient monitoring involves collection of background **water quality** data for specific aquifers as a way to detect and evaluate changes in water quality. Source monitoring is performed in an area surrounding a specific, actual, or potential source of contamination such as a **landfill** or spill site. Enforcement monitoring systems are installed at the direction of regulatory agencies to determine or confirm the origin and concentration gradients of contaminants relative to regulatory compliance. Research monitoring **wells** are installed for detection and assessment of cause and effect relationships between groundwater quality and specific **land use** activities. *See also* Aquifer restoration; Contaminated soil; Drinking-water supply; Hazardous waste siting; Leaching; Water quality standards

Groundwater pollution

When contaminants in **groundwater** exceed the levels deemed safe for the use of a specific **aquifer** use the groundwater is considered polluted. There are three major sources of groundwater **pollution**. These include natural sources, waste disposal activities, and spills, leaks, and **nonpoint source** activities such as agricultural management practices.



All groundwater naturally contains some dissolved salts or minerals. These salts and minerals may be leached from the **soil** and from the aquifer materials themselves and can result in water that poses problems for human consumption, is considered polluted, or does not meet the **secondary standards** for **water quality**. Natural minerals or salts that may result in polluted ground water include chloride, nitrate, fluoride, iron and sulfate.

There are currently no feasible methods for the large-scale disposal of waste that do not have the potential for serious pollution of the **environment**, and there are a number of waste-disposal practices the specifically threaten groundwater. These include activities which range from separate **sewage treatment** systems for individual residences, used by 30% of the population in the United States, to the storage and disposal of industrial wastes. Many of the problems posed by industrial waste arise from the use of surface storage facilities that rely on evaporation for disposal. These facilities are also known as **discharge** ponds, and there are other types in which waste is treated to standards suitable for discharge to surface water. But in the use of both facilities the potential exists for the movement of contaminants into groundwater. Many of the numerous sanitary landfills in the country are in the same situation. Water moving down and away from these sites into groundwater aquifers carries with it a variety of **chemicals** leached from the material deposited in the landfills. The liquid that moves out of landfills is called leachate.

Agricultural practices also contribute to groundwater pollution, and there have been increases in nitrate concentrations and low-level concentrations of pesticides. For control of groundwater pollution, one of the most important agricultural practices is the management of **nitrogen** from all sources--fertilizer, nitrogen fixing plants, and **organic waste**. Once nitrogen is in the nitrate form it is subject to **leaching**, so it is important that the amount applied not exceed the crops' ability to use it. At the same time crops need adequate nitrogen to obtain high yields, and a good balance must be maintained. Low-level **pesticide** contamination occurs in areas where aquifers are sensitive to surface activity, particularly areas of shallow aquifers beneath rapidly **permeable** soils, and regions of "karst" **topography** where deep and wide range pollution can occur due to fractures in the bedrock.

Except in cases of **deep-well injection** waste or substances contained in sanitary landfills, most contaminants move from the land surface to aquifers. The water generally moves through an unsaturated zone, in which biological and chemical processes may act to degrade or change the contaminant. Plant uptake can also act to reduce some of the pollution. Once in the aquifer, how the contaminant moves with the water will depend the solubility of the compound, and the speed of contamination will depend on how fast water moves through the aquifer. Chemical and biological degradation of contaminants can occur in the aquifer, but usually at a slower rate than it does on the surface due to lower temperatures, less available oxygen, and reduced biological activity. In addition aquifer contaminants exist in

Sources of groundwater pollution. (McGraw-Hill Inc. Reproduced by permission.)

lower concentrations, diluted by the large water volume. Most pollution remains relatively localized in aquifers, since movement of the contaminants usually occurs in plumes that have definite boundaries and do not mix with the rest of the water. This does provide an advantage for isolation and treatment.

The types of chemicals that pollute groundwater are as varied as their sources. They range from such simple inorganic materials as nitrate from fertilizers, septic tanks, and **feedlots**, chloride from high salt, and **heavy metals** such as chromium from metal plating processes, to very complex organic chemicals used in manufacturing and household cleaners.

One of the main criteria in judging risk is public health. **Acute effects** from immediate exposure to a concentrated product is often well documented, but little written evidence exists to link physiological effects with long-term chronic exposure. About all that is available are epidemiological data that suggest possible effects, but are by no means conclusive. Environmental effects are even less well understood, but some have suggested that the best way to determine the potential danger is to look at how long a substance persists. Those that remain the longest are most likely to pose long-term risks.

The most efficient way to protect groundwater is to limit activities in recharge areas. For confined aquifers it may be possible to control activities that can result in pollution, but this is extremely difficult for unconfined aquifers which are essentially open systems and subject to effects from any land activity. In areas of potential salt-water intrusion excess pumping can be regulated, and this can also be done where water is being used for **irrigation** faster than the recharge rate, so that the water is becoming saline. Another important activity for the protection of groundwater is the proper sealing of all **wells** that are not currently being used.

Classification of aquifers according to their predominant use is another management tool now employed in a number of states. This establishes water-quality goals and standards for each aquifer, and means that aquifers can be regulated according to their major use. This protects the most valuable aquifers, but leaves the problem of predicting future needs. Once an aquifer is contaminated, it is very expensive if not impossible to restore, and this management tool may have serious drawbacks in the future.

In rural areas of the United States, 95% of the population draws their drinking water from the groundwater supply. With a growing population, continued industrialization, and increasing agricultural reliance on the use of chemicals, many believe it is now more important than ever to protect groundwater. Contamination problems have been encountered in every state, but prevention is far more efficient and effective than restoration after damage has been done. Prevention can be achieved through regional planning and enforcement of state and federal regulations. *See also* Agricultural pollution; Aquifer restoration; Contaminated soil; Drinking-water supply; Feedlot runoff; Groundwater monitoring; Hazardous waste site remediation; Hazardous waste siting; Heavy metals and heavy metal poisoning; Waste management; Water quality; Water quality standards; Water treatment

Growth curve

A graph in which the number of organisms in a population is plotted against time. Such curves are amazingly similar for populations of almost all organisms from bacteria to human beings and are considered characteristic of populations.

Growth curves typically have a sigmoid or S-shaped curve. When a few individuals enter a previously unoccupied area, growth is at first slow during the positive acceleration phase. The growth then becomes rapid and increases exponentially, called the logarithmic phase. The growth rate eventually slows down as environmental **resistance** gradually increases; this phase is called the negative acceleration phase. It finally reaches an equilibrium or saturation level. The final stage of the growth curve is termed the **carrying capacity** of the **environment**.

A good example of a species' growth curve is demonstrated by the sheep population in Tasmania. Sheep were introduced into Tasmania in 1800. Careful records of their numbers were kept, and by 1850 the sheep population had reached 1.7 million. The population remained more or less constant at this carrying capacity for nearly a century.

The figures used to plot a growth curve—time and the total number in the population—vary from one **species** to another, but the shape of the growth curve is similar for all populations. Once a population has become established in a certain region and has reached the equilibrium level, the numbers of individuals will vary from year to year depending on various environmental factors. Comparing these variations for different species living in the same region is helpful to scientists who manage **wildlife** areas or who track factors that affect populations.

For example, a study of the population variations of the snowshoe hare and the lynx (*Lynx canadensis*) in Canada is a classic example of species interaction and interdependence. The peak of the hare population comes about a year before the peak of the lynx population. Since the lynx feeds on the hare, it is obvious that the lynx cycle is related to the hare cycle. This leads to a decline in the population of hares and secondarily to a decline in the lynx population. This permits the plants to recover from the overharvesting by the hares, and the cycle can begin again.

Growth curves are just one of the characteristics of populations. Other characteristics that are a function of the whole group and not of the individual members include population density, birth rate, death rate, age distribution, biotic potential, and rate of dispersion. *See also* Population growth

[*Linda Rehkopf*]

Growth, exponential

see **Exponential growth**

Growth limiting factors

There are a number of essential conditions which all organisms, both plants and animals, require to grow. These are known as growth factors. Plants, for example, require sunlight, water, and **carbon dioxide** in order to perform **photosynthesis**. They require nutrients such as **nitrogen**, **phosphorus**, and various trace elements in order to form tissues. The **environment** in which the plant is growing does not contain a unlimited supply of these growth factors. When one or more of them is present in levels or concentrations low enough to constrain the growth of the plant, it is known as a growth limiting factor. The rate or magnitude of the growth of any organism is controlled by the growth factor that is available in the lowest quantities. This concept is analogous to the saying that a chain is only as strong as its weakest link.

These factors limit **population growth**. If they did not exist, a population could increase exponentially, limited only by its own intrinsic lifespan. Growth limiting factors are essential to the traditional concept of **carrying capacity**, which rests on the assumption that the available resources limit the population that can be sustained in that area. Advances in technology have enabled people to increase the carrying capacity in certain areas by manipulating the growth limiting factors. Perhaps the best example of this is the use of fertilizers on farmland.

In the field of population **ecology**, identifying growth limiting factors is part of establishing the constraints and pressures on populations and predicting growth in various conditions. Algal growth in New York Harbor provides an example of the importance of identifying growth limiting factors. In New York Harbor, several billion gallons of untreated **wastewater** are released daily, bringing enormous quantities of nutrients and suspended solids into the water. Algae in the harbor take advantage of the **nutrient** loads and grow more than they would under nutrient-poor conditions. At the same time, however, the suspended solids and silts brought into harbor cause the water to become very turbid, limiting the amount of sunlight that penetrates it. Sunlight is rarely a growth limiting factor for algae; nutrients are usually what limits their growth, but in this case nutrients are in excess supply. This means that if **pollution control** in the harbor ever results in control of the turbidity in the water, there will probably be a sharp increase in the growth of algae.

Consideration of growth limiting factors is also very important in the field of **conservation biology** and **habitat** protection. If the goal is to protect a bird such as the heron, which may feed on fish from a lake and nest in upland trees nearby, limiting factors must be taken into account not only for the growth of the individual but also for the population. **Conservation** efforts must not be directed only toward ensuring there are enough fish in the lake. Enough trees must also be left uncut and undisturbed for nesting in order to address all of the growth requirements for the population. Regardless of how abundant the fish are, the number of herons will only grow to the extent allowed by the number of available nesting sites.

Environmentalists use growth limiting factors to distinguish between undisturbed ecosystems and unstable or stressed systems. In an **ecosystem** that has been distressed or disturbed, the nature of growth limiting factors changes, and these changes are often human-induced, as they are in New York Harbor. Though the change in circumstances may not always appear negative in impact, it still represents a shift away from the original balance, and it may have effects on other **species** or lead to subtle long-term changes in the system. Any cleanup or management strategy must use these new growth limiting factors to identify the nature of the imbalance that has occurred and develop a procedure to restore the system to its original condition.

Growth limiting factors are extensively used in the field of **bioremediation**, in which **microbes** are used to clean up environmental contaminants by breakdown and **decomposition**. **Oil spills** are a good example. Bacteria that can break down and degrade oils are naturally present in small quantities in **soil**, but under normal conditions their growth is limited by both the availability of essential nutrients and the availability of oil. In the event of an oil spill on land, the only growth limiting factor for these bacteria is nutrients. Bioremediation scientists can add nitrogen and phosphorus to the soil in these circumstances to stimulate growth, which increases degradation of the oil. Techniques such as these, which use naturally occurring bacterial populations to control contamination, are still in development; they are most useful when the contaminants are present in high concentrations and confined to a limited area. *See also* Algal bloom; Decline spiral; Ecological productivity; Exponential growth; Food chain/web; Restoration ecology

Guinea worm eradication

In 1986, the world health community began a campaign to eliminate the guinea worm (*Dracunculus medinensis*) from the entire world. If successful, this will be only the second global disease ever completely eradicated (smallpox, which was abolished in 1977 was first), and the only time that a human parasite will have been totally exterminated worldwide. Known as the fiery serpent, the guinea worm has been a terrible scourge in many tropical countries. Dracunculiasis (pronounced dra-KUNK-you-LIE-uh-sis) or guinea worm disease starts when people drink stagnant water contaminated with tiny copepod water fleas (called cyclops) containing guinea worm larvae. Inside the human body, the worms grow to as long as 3 ft (1 m). After a year of migrating through the body, a threadlike adult worm emerges slowly through a painful skin blister. Most worms come out of the legs or feet but they can appear anywhere on the body. The eight to 12 weeks of continuous emergence are accompanied by burning pain, fever, nausea, and vomiting. Many victims bathe in a local pond or stream to soothe their fever and pain. When the female worm senses water, she releases tens of thousands of larvae, starting the cycle once again. Once the worms become established in local ponds, infections among people living nearby are at high risk for further infections.

As the worm emerges from the wound, it can be rolled around small stick and pulled out a few centimeters each day. Sometimes the entire worm can be extracted in a few days, but the process usually takes weeks. Unfortunately, if you pull too fast and the worm breaks off, the part left in your body can die and fester, leading to serious secondary infections. If the worm comes out through a joint, permanent crippling can occur. There is no cure for guinea worm disease once the larvae are ingested. There is no vaccine, and having been infected once doesn't give you immunity. Many people in affected villages suffer the disease repeatedly year after year. The only way to break the cycle is through behavioral changes. Community health education, providing clean water from **wells** or by filtering or boiling drinking water, eliminating water fleas by chemical treatment, and teaching infected victims to stay out of drinking supplies are the only solutions to this dreadful problem.

Although people rarely die as a direct effect of the parasite, the social and economic burden at both the individual and community level is great. During the weeks that worms are emerging, victims usually are unable to work or carry out family duties. This debilitation often continues for several months after worms are no longer visible. In severe cases, arthritis-like conditions can develop in infected joints, and the patient may be permanently crippled.

When the eradication campaign was started in 1986, guinea worms were endemic to 16 countries in sub-Saharan Africa as well as Yemen, India, and Pakistan. Every year about 3.5 million people were stricken and at least 100 million people were at risk. With the leadership of former U.S. President Jimmy Carter, a consortium of agencies, institutions, and organizations—the World Health Organization (WHO), UNICEF, the United Nations Development Program (UNDP), the **World Bank**, bilateral aid agencies, and the governments of many developed countries—banded together to fight this disease. Although complete success has not yet occurred, encouraging progress has been made. Already the guinea worm infections are down more than 96%. Pakistan was the first formerly infested country to be declared completely free of these **parasites**. Infection rates in Kenya, Senegal, Cameroon, Chad, India, and Yemen are down below 100 cases per year. More than 80% of all remaining cases occur in Sudan, where civil war, poverty, **drought**, and governmental **resistance** to outside aid have made treatment difficult.

An encouraging outcome of this crusade is the demonstration that public health education and community organization can be effective, even in some of the poorest and most remote areas. Village-based health workers and volunteers conduct disease surveillance and education programs, allowing funds and supplies to be distributed in an efficient manner. Once people understand how the disease spreads and what they need to do to protect themselves and their families, they do change their behavior. A great advantage of this community health approach is educating villagers about the importance of proper **sanitation** and clean drinking water is effective not only against dracunculiasis, but also can help eliminate **malaria**, shistosomiasis, and many other water-borne diseases.

Gulf War syndrome

Approximately 697,000 U.S. service members were deployed to the Persian Gulf from January to March 1991 as part of a multinational effort to stop Iraq's attack against Kuwait. And while the war itself was short, a long battle has been taking place ever since by veterans, the government and scientists to determine what has caused "Gulf War Syndrome," a mysterious collection of symptoms reported by as many as 70,000 U.S. men and women who served in the war. They are joined by British veterans in their health complaints, and in smaller numbers by Canadians, Czechs, and Slovaks.

Gulf War Syndrome is a complex array of symptoms, including chronic fatigue, rashes, headaches, diarrhea, sleep disorders, joint and muscle pain, digestive problems, memory loss, difficulty concentrating, and depression. A small percentage of veterans have had babies born with twisted limbs, congestive heart failure, and missing organs. The veterans blamed these abnormalities on their service in the Gulf. The U.S. **Environmental Protection Agency** (EPA) has also found high rates for brain and nervous system cancers among these veterans, up to seven to 14 times higher than among the general population, depending on the age group. Considering that most soldiers and veterans are younger and in better physical shape than the general population, researchers find such figures more than surprising.

Collectively, these ailments suggest that neurological processes may have been altered, or immune systems damaged. While no single cause has been identified, various analyses of the Gulf War experience point to low-level exposure of chemical weapons, combined with other environmental and medical factors, as key contributors to the health problems triggered years after exposure.

The war was unique in the levels of physical and emotional stresses created for those who served, as well as for their families. A significant portion of troops were from the reserves, rather than active enlistees. Deployment occurred at unprecedented speed. Most troops were given multiple vaccinations that singularly do not have adverse effects; their combined effects were not tested before distribution. Detectors often signaled the presence of chemical weapons during the conflict, but were mostly ignored as inaccurate. The soldiers worked long hours in extreme temperatures, lived in crowded and unsanitary conditions where pesticides were used indiscriminately to rid areas of flies, snakes, spiders, and scorpions, and breathed and had dermal exposures to **chemicals** from the continuous oil fires—burning trash, feces, fuels, and solvents. Blazing sun, blowing sand and biting sandflies further increased the discomfort and stress of military life in the **desert**. Exposures to the various fumes often exceeded federal standards and World Health Organization health guidelines; these alone could have caused "permanent impairment," according to a 1994 National Institutes of Health report.

The U.S. military now admits it was inadequately prepared for chemical and biological warfare, which it knew Iraq had previously used. Three of four reserve units, for example, didn't have protective gear. The drug pyridostigmine bromide (PB, 3-dimethylaminocarbonyloxy-N-methylpyridium bromide) was given to almost 400,000 troops before and during the Gulf War to combat the effects of nerve gas, even though it is approved by the **Food and Drug Administration** (FDA) only for treatment of the neurological disorder myasthenia gravis. The FDA agreed on the condition that commanders inform troops what they were taking and what the potential side effects were. One survey, however, found that 63 of 73 veterans who had taken the drug did not receive such information. Records were not kept on who took which drugs or vaccines, as required by FDA and Defense Department guidelines.

While the Defense Department and other government agencies have spent more than $80 million to try to identify the cause of veterans' ailments, a privately funded team of toxicologists and epidemiologists may have discovered an explanation for at least some problems experienced by Gulf War veterans. Researchers treated chickens in 1996 with nonlethal doses of three chemicals veterans were exposed to: DEET (N,N-diethyl-m-toluamide) and chlorpyrifos (O,O-diethyl O-3,5,6-trichloropyridinyl phosphorothioate), used topically or sprayed on uniforms as insecticides, and the anti-nerve gas drug pyridostigmine bromide. They found that simultaneous exposure to two or more of the insecticides and drugs damaged the chickens' nervous system, even though none of the chemicals caused problems by itself. The range of symptoms the chickens developed is similar to those the veterans describe. A similar study by the Defense Department found that the chemicals were more toxic to rats when given together than individually. Follow up studies are underway to determine if this also holds for humans.

The researchers hypothesize that multiple chemicals overwhelmed the animals' ability to neutralize them. The **enzyme** butyrylcholinesterase, which circulates in the blood, breaks down a variety of nitrogen-containing organic compounds, including the three substances tested. But the anti-nerve gas drug, in particular, can monopolize the enzyme, preventing it from dealing with the insecticides. Those chemicals could then sneak into the brain, and cause damage they would not produce on their own.

Many veterans believe that, while the drugs and pesticides may have played a role in their ailments, so have chemical weapons. Troops could have been subjected to much more low-level exposure of chemical weapons than previously believed, either directly or via air plumes, because

75% of Iraq's chemical weapons production capability, along with 21 chemical weapons storage sites, were destroyed by allied air raids.

In addition, U.S. battalions blew up an Iraqi arms dump soon after the war was over, before many troops had left the Gulf. Khamisiyah, an enormous ammunition storage site, covered 20 mi^2 (50 km^2) with 100 ammunition bunkers and other storage facilities. Two large explosions were set off, one on March 4 and a second on March 10, 1991. Smaller demolition operations continued in the area through most of April 1991.

While the site was not believed to have contained chemical weapons at the time, the Defense Department admitted in June 1996 that the complex had included nerve and mustard gases. The Central Intelligence Agency also admitted in April 1997 that it knew in 1986 that thousands of mustard gas weapons had been stored at the Khamisiyah depot, but the agency failed to include it on a list of suspected sites provided to the Defense Department before the 1991 war, which led troops to assume it was safe to blow it up.

Weather data shows that upper-level winds in the gulf were blowing in a southerly direction during and after the bombing. Thus, vapors carried by these winds could have contaminated troops hundreds of miles away. A 1974 report, *Delayed Toxic Effects of Chemical Warfare Agents*, found that chemicals weapons plant workers suffer as many chronic symptoms as those now suffered by Gulf War veterans, including neurological, gastrointestinal and heart problems, loss of memory and a greater risk of **cancer**; exposure to these chemicals may also create birth effects in children. A 1995 study by a British medical researcher found many of the same symptoms in **Third World** people exposed to **organophosphate** insecticides, like DEET used in the Gulf War, which are diluted versions of chemical weapons.

While British, Canadian and Slovak veterans have reported similar ailments, albeit in smaller numbers, no French veterans have complained of such illnesses, despite extensive publicity. This is also providing valuable clues to the U.S. veterans' maladies, in several ways. For example, the French did not use many of the vaccines that the British and Americans used, including pyridostigmine bromide. French camps were not sprayed with insecticides as a preventive measure, rather only when needed to control **pest** populations. When they did spray, they did not use organophosphates. Finally, the French were nowhere near the Khamisiyah munitions depot when the destruction occurred.

In February 1997, a series of study results established the most definitive links between Gulf War syndrome and chemicals to date. The research identifies six "syndromes," or clusters of like symptoms in discrete groups of veterans, and associates each with distinct events during the war. Troops who reported exposure to chemical weapons, for example, are likely to suffer from confusion, balance problems, impotence and depression. Other sets of symptoms correspond to the use of insect repellants and anti-nerve gas drugs. While not conclusive, these findings will likely spur further research into the effects of low-level exposure to certain chemicals.

Such research was advocated by the presidential advisory committee, a 12-member panel of veterans, scientists, and health care and policy experts established in 1995. The committee held 18 public meetings between August 1995 and November 1996 to investigate the nature of Gulf War veterans' illnesses, health effects of Gulf War risk factors, and the government's response to Gulf War illnesses. While the committee's final report in January 1997 concluded that no single, clinically recognizable disease can be attributed to Gulf War service, it recommended additional research on the long-term health effects of low-level exposures to chemical weapons, on the synergistic effects of pyridostigmine bromide with other Gulf War risk factors, and on the body's physical response to stress.

While the debate continues, the Veterans Affairs and the Defense Departments are providing free medical help to any veteran who believes he or she is suffering from Gulf War Syndrome. In January 1997, President Clinton proposed new regulations that would extend the time available to veterans to prove their disabilities are related to Gulf War service from two to 10 years. He also initiated a presidential review to ensure that in any future deployments the health of service men and women and their families is better protected.

Definitive answers as to the causes and treatments for veterans' ailments may be years away. What is clear is that the complex biological, chemical, physical and psychological stresses of the **Persian Gulf War** appear to have produced a variety of complex adverse health effects. No single disease or syndrome is apparent, but rather multiple illnesses with overlapping symptoms and causes. If what had been considered acceptable trace levels of chemical agents in the war **environment** are found to be harmful, the U.S. military will have to revamp the way it protects its forces against even those tiny amounts. Tragically, that would mean that not only did "friendly fire" account for nearly 25% of the 146 U.S. deaths, but also that allied actions were responsible for the war's most persistent and haunting pain.

Gullied land

Areas where all diagnostic **soil** horizons have been removed by flowing water, resulting in a network of V-shaped or U-shaped channels. Generally, gullies are so deep that extensive reshaping is necessary for most uses. They cannot be crossed with normal farm machinery. While gullied land can occur on any land, they are often most prevalent on loess, sandy, or other soils with low cohesion. *See also* Erosion; Soil profile; Soil texture

Gypsy moth

The gypsy moth (*Portheria dispar*), a native of Europe and parts of Asia, has been causing both ecological and economic damage in the eastern United States and Canada since its introduction in New England in the 1860s.

In 1869, french entomologist Leopold Trouvelet brought live specimens of the insect to Medford, Massachusetts for experimentation with silk production. Several individual specimens escaped and became an established popula-

Gypsy moth females laying eggs. (Photograph by Michael Gadumski. Photo Researchers Inc. Reproduced by permission.)

tion over the next 20 years. The destructive abilities of the gypsy moth became readily apparent to area residents, who watched large sections of forest be destroyed by the larvae. From the initial infestation in Massachusetts, the gypsy moth spread throughout the northeastern United States and southeastern Canada. As of 2001, the following states were quarantined: Connecticut, Delaware, Maryland, Michigan, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Vermont. More that two-thirds of Virginia is quarantined, as well as sections of Ohio, Indiana, Maine, North Carolina, Wisconsin, and Wyoming. The U. S. Department of Agriculture reports that virtually all areas that have experienced an invasion of gypsy moths continue to have extremely high levels of infestation.

Gypsy moths have a voracious appetite for leaves, and the primary environmental problem caused by them is the destruction of huge areas of forest. Gypsy moth caterpillars defoliate a number of **species** of broadleaf trees including birches, larch, and aspen, but prefer the leaves of several species of oaks, though they have also been found to eat some evergreen needles. One caterpillar can consume up to one square foot of leaves per day. In 2001, 84.9 million acres (34.4 million ha) had been defoliated by these insects. The sheer number of gypsy moth caterpillars produced in one generation can create other problems as well. Some areas become so heavily infested that the insects have covered houses and yards, causing psychological difficulties as well as physical.

There are few natural predators of the gypsy moth in North America, and none that can keep its population under control. Attempts have been made since the 1940s to control the insect with pesticides, including DDT, but these efforts have usually resulted in further contaminating of the **environment** without controlling the moths or their caterpillars. Numerous attempts have also been made to introduce species from outside the region to combat it, and almost 100 different natural enemies of the gypsy moth have been introduced into the northeast United States. Most of these have met, at best, with limited success. Recent progress has been made in experiments with a Japanese fungus that attacks and kills the gypsy moth. The fungus enters the body of the caterpillar through its pores and begins to destroy the insect from the inside out. It is apparently non-lethal to all other species in the infested areas, and its use has met with limited success in parts of Rhode Island and upstate New York. It remains unknown however, whether it will control the gypsy moth, or at least stem the dramatic population increases and severe infestations.

H

Arie Jan Haagen-Smit (1900 – 1977)

Dutch atmospheric chemist

The discoverer of the causes of **photochemical smog**, Haagen-Smit was one of the founders of atmospheric chemistry, but first made significant contributions to the chemistry of essential oils. Haagen-Smit was born in Utrecht, Holland, in 1900, and graduated from the University of Utrecht. He became head assistant in organic chemistry there and later, served as a lecturer until 1936. He came to the United States as a lecturer in biological chemistry at Harvard, then became associate professor at the California Institute of Technology in Pasadena. He retired as Professor of Biochemistry in 1971, having served as executive officer of the department of biochemistry and director of the plant **environment** laboratory. Haagen-Smit also contributed to the development of techniques for decreasing **nitrogen** oxide formation during **combustion** in electric **power plants** and autos, and to studies of damage to plants by **air pollution**.

While early workers on the **haze** and eye irritation that developed in Los Angeles, California, tried to treat it as identical with the **smog** (**smoke** + fog) then prevalent in London, England, Haagen-Smit knew at once it was different. In his reading, Haagen-Smit had encountered a 1930s Swiss patent on a process for introducing random oxygen functions into **hydrocarbons** by mixing the hydrocarbons with nitrogen dioxide and exposing the mixture to ultraviolet light. He thought this mixture would smell much more like a smoggy day in Los Angeles than would some sort of mixture containing **sulfur dioxide**, a major component of London smog. He followed the procedure and found his supposition was correct. Simple analysis showed the mixture now contained **ozone**, organic peroxides, and several other compounds. These findings showed that the sources of the problems of Los Angeles were **petroleum** refineries, **petrochemical** industries, and ubiquitous **automobile** exhaust.

Haagen-Smit was immediately attacked by critics, who set up laboratories and developed instruments to prove him wrong. Instead the research proved him right, except in minor details.

Haagen-Smit had a long and distinguished career. In addition to his work on the chemistry of essential flower oils and famous findings on smog, he also contributed to the chemistry of plant hormones and plant alkaloids and the chemistry of **microorganisms**. He was a founding editor of the *International Journal of Air Pollution*, now known as *Atmospheric Environment*, one of the leading air **pollution** research journals. Though he found the work uncongenial, he stayed with it for the first year, then retired to the editorial board, where he served until 1976.

Once it was obvious that he had correctly identified the cause of the Los Angeles smog, he was showered with honors. These included membership in the National Academy of Science, receipt of the Los Angeles County Clean Air Award, the Chambers Award of the **Air Pollution Control** Association (now the **Air and Waste Management Association**), the Hodgkins Medal of the Smithsonian Institution, and the National Medal of Science. In his native Netherlands he was made a Laureate of Labor by the Netherlands Chemical Society, and Knight of the Order of Orange Nassau.

Habitat

Refers to the type of **environment** in which an organism or **species** occurs, as defined by its physical properties (e.g., rainfall, temperature, topographic position, **soil texture**, **soil** moisture) and its chemical properties (e.g., soil acidity, concentrations of nutrients and **toxins**, oxidation reduction status). Some authors include broad biological characteristics in their definitions, for instance forest versus **prairie** habitats,

referring to the different types of environments occupied by trees and grasses. Within a given habitat there may be different micro-habitats, for example the hummocks and hollows on bogs or the different soil horizons in forests.

Habitat conservation plans

Protection of the earth's **flora** and **fauna**, the myriad of plants and animals that inhabit our planet, is totally dependent upon preserving their habitats. This is because a **habitat**, or natural **environment** for a specific variety of plant or animal, provides everything necessary for sustaining life for that **species**. Habitat **conservation** is part of a larger picture involving interdependency between all living things. Human life has been sustained since its dawning through the utilization of both plants and animals for food, clothing, shelter and medicines. It follows then that the destruction of any specie's environment, which will result in the eventual destruction of the species itself, adversely affects us all.

Habitat destruction occurs for a number of reasons. Human industry has usually resulted in **pollution** that has often destroyed the balance of natural elements in **soil**, water and air that are necessary to life. The need for forest products such as lumber has threatened woodlands in more ways than one. A lumbering practice called **clear-cutting**, in addition to over-harvesting a forest, leaves behind barren ground that results in **erosion** and threatens species dependent on the vegetation that grows on the forest floor. This wearing away of soil often results in negative changes to nearby streams and thus the water supply to multitudes of living things. The introduction of non-native species into an area can also threaten a habitat, as plants and animals with no natural enemies may thrive abnormally. This in turn will throw off the delicate balance and natural biological controls on **population growth** that each environment provides for its inhabitants.

As the understanding of these facts became more widespread, the demand for habitat conservation throughout the world increased. In the United States, in 1973, Congress passed the **Endangered Species Act** to protect both at risk species and their environments. In order to control activities by private and non-federal government landowners that might disturb habitats, the Act included a section outlining Habitat Conservation Plans (HCPs).

These HCPs were not implemented without a good deal of controversy. Some environmentalists were critical of the plans, believing that they failed to actually preserve the habitats and species they were designed to protect. Both conservationists and landowners and industrialists argued that these HCPs' were based upon faulty science and invalid and insufficient data. Impartial reviews did indicate that there were flaws. One cited weakness was that a species could theoretically be added to the endangered list but have no modification made in the plan to protect that species' living-space.

It is clearly a measure of this controversy that in the law's first twenty years, only fourteen such plans were developed and approved nationwide. During the administration of President Bill Clinton, the federal government revised policies to encourage more numerous and more effective HCP applications. A more responsive to change *"No surprises"* policy helped encourage participation in habitat conservation plans.

This policy recognizes that **natural resources** change and environments require continual monitoring and alterations in plans, that those trying to balance environments can do so with **adaptive management**. Such alterations encouraged participation in HCPs, and by 1997, more than 200 plans covering nine million acres of land had been approved. As of April of 2002, the United States **Fish and Wildlife Service** notes that nearly double that number, 379 plans covering nearly 30 million acres and protecting more than 200 endangered and threatened species have now been approved.

One positive example of the possibilities created by such plans is the work of the Plum Creek Timber Company, a nationwide timberland company whose corporate offices are located in Seattle, Washington. Self-described as "the second largest private timberland owner in the United States, with 7.8 million acres located in the northwestern, southern and northeastern regions of the country", the company lists many initiatives it has undertaken to preserve the environments under its charge. In the early 1990's, Plum Creek Timber Company developed a plan to provide a *ladder-like* framework in Coquille River tributaries in Oregon to aid fish in reaching upper areas blocked for many years by a culvert. Spawning surveys completed the next year showed that coho **salmon** and steelhead trout, for the first time in forty years, were present above the culvert.

HCPs were created to focus attention on the problem of declining **wildlife** on land not owned and protected by the federal government and to attempt to maintain the **biodiversity** so necessary for all life. This goal would ideally assure that land is developed in such a way that it serves both the needs of the landowner and of threatened wildlife. However, in reality, it is not always possible to achieve such a goal. Often the more appropriate aim, if habitat conservation is to be successful, will be total protection of a wildlife environment even at the price of banning all development.

Habitat fragmentation

The **habitat** of a living organism, plant, animal, or microbe, is a place, or a set of environmental conditions, where the organism lives. Net loss of habitat obviously has serious implications for the survival and well-being of dependent organisms, but the nature of remaining habitat is also very important. One factor affecting the quality of surviving habitat is the size of remaining pieces. Larger areas tend to be more desirable for most **species**. Various influences, often a result of human activity, cause habitat to be divided into smaller and smaller, widely separated pieces. This process of habitat fragmentation has profound implications for species living there.

Each patch created when larger habitat areas are fragmented results in more edge area where patches interface with the surrounding **environment**. These smaller patches with a relatively large ratio of edge to interior area have some unique characteristics. They are often distinguished by increased predation when predators are able to hunt or forage along this edge more easily. The decline of songbirds throughout the United States is due in part to the increase of the brown-headed cowbird competing with other birds along habitat edges. The cowbird acts as a parasite by laying its eggs in other birds' nests and leaving them for other birds to hatch and raise. After hatching, the young cowbirds compete with the smaller birds of the nest, almost always killing them.

In the smaller patches formed from fragmentation, habitat is less protected from adverse environmental events, and a single storm may destroy the entire area. A disease outbreak may eliminate the entire population. When the number of breeding adults becomes very low, some species can no longer reproduce successfully.

Some songbirds found in the United States are declining in number as their habitat shrinks or disappears. When they migrate south in the winter they find that habitat is more scarce and fragmented. When they return from the tropics in the spring, they discover that the nesting territory that they used the previous year has disappeared.

Species dispersal is decreased as organisms must travel farther to go from one habitat area to another, increasing their exposure to predation and possibly harmful environmental conditions. Populations become increasingly insular as they become separated from related populations, losing the genetic benefits of a larger interbreeding population.

Road building often divides habitat areas, seriously disrupting **migration** of some mammals and herptiles (**frogs**, snakes, and turtles). Large swaths of land used by modern freeways are particularly effective in this regard. In earlier times, railroads built across the Great Plains to connect the west coast of the United States with states east of the Mississippi, divided **bison** habitat and hampered their migration from one grazing area to another. This was one of the factors that led to their near **extinction**.

Habitat fragmentation, usually a result of human activity, is found in all major habitat types around the world. Rain forests, **wetlands**, **grasslands**, and hardwood and conifer forests are all subject to various degrees of fragmentation. Globally, rain forests are currently by far the most seriously impacted **ecosystem**. Because they contain 50% or more of the world's species, the resulting number of species extinctions is particularly disturbing. It is estimated that 25% of the world's rainforests disappeared during the twentieth century, and another 25% were seriously fragmented and degraded. In the last two centuries, nearly all of the **prairie** grassland once found in the United States has disappeared. Remaining remnants occur in small, scattered, isolated patches. This has resulted in the extinction or near extinction of many plant and animal species.

Ability to survive habitat fragmentation and other environmental changes varies greatly among species. Most find the stress overwhelming and simply disappear. A few of the common species that have been very successful in adapting to changing conditions include animals such as the opossum, raccoon, gray squirrel, and European starling. Plant examples include dandelions, crab grass, creeping Charlie, and many other weed species. The wetland invader, **purple loosestrife**, originally imported from Europe to the United States, is rapidly spreading into disrupted habitat previously occupied by native emergent aquatic vegetation such as reeds and cattails. Animal species that once found a comfortable home in cattail stands must move on.

Ernst Heinrich Philipp August Haeckel (1834 – 1919)

German naturalist, scientist, biologist, philosopher, and professor

Ernst Haeckel was born in Potsdam, Germany. As a young boy he was interested in **nature**, particularly botany, and kept a private herbarium, where he noticed that plants varied more than the conventional teachings of his day advocated. Despite these natural interests, he studied medicine—at his father's insistence—at Würzburg, Vienna, and Berlin between 1852 and 1858. After receiving his license he practiced medicine for a few years, but his desire to study *pure science* won over, and he enrolled at the University of Jena to study zoology. Following completion of his dissertation, he served as professor of zoology at the university from 1862 to 1909. The remainder of his adult life was devoted to science.

Haeckel was considered a liberal non-conformist of his day. He was a staunch supporter of Charles Darwin, one of his contemporaries. Haeckel was a prolific researcher and writer. He was the first scientist to draw a "family tree" of animal life, depicting the proposed relationships between various animal groups. Many of his original drawings are still used in current textbooks. One of his books, The Riddle of the Universe (1899), exposited many of his theories on **evolution**. Prominent among these was his theory of recapitulation, which explained his views on evolutionary vestiges in related animals. This theory, known as the *Biogenic Law*, stated that "ontogeny recapitulates phylogeny"—the development of the individual (ontogeny) repeats the history of the race (phylogeny). In other words, he argued that when an embryo develops, it passes through the various evolutionary stages that reflect its evolutionary ancestry. Although this theory was widely prevalent in biology for many years, scientists today consider it inaccurate or only partially correct. Some even argue that Haeckel falsified his diagrams to prove his theory.

In **environmental science**, Haeckel is perhaps best known for coining the term **ecology** in 1869, which he defined as "the body of knowledge concerning the economy of nature—the investigation of the total relationship of the animal both to its organic and its inorganic **environment** including, above all, its friendly and inimical relations with those animals and plants with which it directly or indirectly comes into contact—in a word, ecology is the study of all those complex interrelations referred to by Darwin as the conditions for the struggle for existence."

Half-life

A term primarily used to describe the physical half-life, how **radioactive decay** processes cause unstable atoms to be transformed into another element, but can also refer to the biological half-life of substances that are not radioactive.

Specifically, the physical half-life is the time required for half of a given initial quantity to disappear (or be converted into something else). This description is useful because radioactive decay proceeds in such a way that a fixed

percentage of the atoms present are transmuted during a given period of time (a second, a minute, a day, a year). This means that many atoms are removed from the population when the total number present is high, but the number removed per unit of time decreases quickly as the total number falls.

For all practical purposes, the number of radioactive atoms in a population never reaches zero because decay affects only a fraction of the number present. Some infinitesimal number will still be present even after an infinite number of half-lives because with each time period half of what was present before decays and is lost from the sample. Therefore, determining the point at which half of the original number disappears (the half-life) is usually the most accurate way of describing this process. *See also* Radioactivity

Halons

Halons are **chemicals** that contain **carbon**, fluorine, and **bromine**. They are used in fire extinguishers and other firefighting equipment. Because of their bromine content, halons can destroy **ozone** molecules(O_3) very effectively, thereby contributing to the depletion of ozone and the creation of holes in the ozone layer of the **stratosphere**. The ozone layer is located 10–28 mi (16–47 km) above the surface of the earth and it protects humans and the **environment** from the Sun's ultraviolet-B radiation. Halons account for approximately 20% of the ozone depletion.

Halons have been used since the 1940s, when they were discovered by U.S. Army researchers looking for a fire-extinguishing agent to replace carbon tetrachloride. Halons are very effective against most types of fires, are nonconductive, and dissipate without leaving a residue. They are also economical, very stable, and safe for human use.

Halons consist of carbon atom chains with attached **hydrogen** atoms that are replaced by the halogens fluorine (F)and bromine (Br). Some also contain **chlorine** (Cl). Halon-1211 ((bromochlorodifluoromethane, CF_2ClBr), halon-1301 (bromotrifluoromethane, CF_3Br), and halon-2402 (dibromotetrafluoroethane, $C_2F_4Br_2$) are the major fire-suppressing halons. Halon-1211 is discharged as a liquid and vaporizes into a cloud within a few feet. Halon-1301 is stored as a liquid but discharges as a gas. Halons suppress fires because they bond with the free radicals and intermediates of the decomposing fuel molecules that propagate fire, thus rendering the fuel inert. They also lower the temperature the fire.

Halons may take up to seven years to drift up and distribute themselves throughout the stratosphere, with the highest concentrations over the poles. High-energy **ultraviolet radiation** breaks their bromine and chlorine bonds thus releasing these very reactive halogen molecules, which in turn break down the ozone molecules and react with free oxygen to interfere with ozone creation. Although chlorine is more abundant, bromine is more than 100 times more damaging to ozone.

Halons are categorized as class I ozone-depleting substances, along with **chlorofluorocarbons** (CFCs) and other substances with ozone-depleting potentials (ODPs) of 0.2 or greater. The Ozone Depletion Potential(ODP)is a number that refers to the amount of ozone depletion caused by a substance. Halon-1211 has an ODP of 3.0 and an atmospheric lifetime of 11 years. It also has a global warming potential (GWP) of 1300. Halon-1301 has an ODP of 10.0, an average lifetime of 65 years, and a GWP of 5600 to 6900. Halon-2402 has an ODP of 6.0. In contrast, CFC-11, a common refrigerant, has an ODP of 1. Halon-1211 and halon-1301 are the most common halons in the United States. Halon-2402 is widely used in Russia and the developing world. Although total halon production between 1986 and 1991 accounted for only about 2% of the total production of class I substances, it accounted for about 23% of the ozone depletion caused by class I substances.

Halon production in the United States ended on December 31, 1993 because they contribute to ozone depletion. Under the Montreal Protocol on Ozone Depleting Substances, first negotiated in 1987 and now including more than 172 countries, halons became the first ozone-depleting substances to be phased out in industrialized nations, with production stopped in 1994. Under the **Clean Air Act**, the United States banned the production and importation of halons as of January 1, 1994. The use of existing halons in fire protection systems continues and recycled halons can be purchased to recharge such systems. It is estimated that about 50% of all halons ever produced currently exist in portable fire extinguishers and firefighting equipment. The United States holds 40% of the world's supply of halon-1301. In 1997, approximately 1,080 tons (977 metric tons) of halon-1211 and 790 tons (717 metric tons) of halon-1301 were released in the United States. In 1998, the U.S. **Environmental Protection Agency** (EPA) prohibited the venting of halons during training, testing, repair, or disposal of equipment, and banned the blending of halons, to prevent the accumulation of nonrecyclable stocks.

The **European Union** has gone beyond the Montreal Protocol, banning the sale and non-critical use of halons after December 31, 2002, and requiring the decommissioning of non-critical halon systems by December 31, 2003.

Halon production and consumption continues in developing countries, especially China, the Republic of Korea, India, and Russia. Under the Montreal Protocol, developing countries were to freeze halon consumption by January 2002. A 50% reduction in halon consumption is required by January 2005 and the complete halt of halon production and use is slated for January 2010. However halon-1211 emissions increased by about 25% between 1988 and 1999. Since most of the increased manufacture and release of halon-1211 occurs in China, the **United Nations Environment Programme** is helping China to phase-out production by 2006.

Atmospheric levels of halon-1202, which is not covered by the Montreal Protocol, increased fivefold between the late 1970s and 1999, and by 17% annually in the late 1990s. It is not known whether this increase is a byproduct of the inefficient production of other halons in developing countries or whether some countries are manufacturing it for military applications. Halon-1202's ODP is about one-half that of the common CFCs.

Alternatives are now available for most halon applications. Existing halon supplies from fire suppression systems are being recycled for critical uses where no alternative exists.

Hanford Nuclear Reservation

The Hanford Engineering Works was conceived in June 1942 under the direction of Major General Leslie R. Groves, head of the famous Manhattan Project, to produce **plutonium** and other materials for use in the development of **nuclear weapons**. By December 1942, a decision was reached to proceed with the construction of three plants—two to be located at the Clinton Engineering Works in Tennessee and a third at the Hanford Engineering Works in Washington.

Hanford was established in the southeastern portion of Washington state between the Yakima Range and the Columbia River, about 15 mi (24 km) northwest of Pasco, Washington. The site occupies approximately 586 mi^2 (1,517 km^2) of **desert** with the Columbia River flowing through its northern region. Once a linchpin of United States nuclear weapons production during the Cold War era, Hanford has now become the world's largest environmental cleanup project.

Hanford Engineering Works, known as HEW or "site W" in classified terms, was originally under the control of the Manhattan District of the **Army Corps of Engineers** (MED) until the **Atomic Energy Commission** (now the Department of Energy, DOE) took over in 1947. The actual operation of the site has been managed by a series of contractors since its inception. The first organization granted a contract to run site operations at Hanford was E.I. DuPont de Nemours and Company. In 1946, General Electric took over, and with the aid of several subcontractors ran construction and operation of the site through 1965. A series of contractors have directed operations at both the main DOE-Richland Operations Office and the DOE-Office of River Protection (ORP), the agency responsible for overseeing **hazardous waste** tank farm clean up along the Columbia River, since then.

In 1965, Battelle Memorial Institute, a non-profit organization, assumed management of the federal government's DOE research laboratories on the Hanford Site. The newly formed Pacific Northwest Laboratory (which became Pacific Northwest National Laboratory, or PNNL, in 1995) supports the Hanford site cleanup through the development and testing of new technologies. Battelle still runs the PNNL today.

A number of contractors have directed operations at HEW throughout its history. As of early 2002, the prime contractors at the DOE-Richland Operations Office included Battelle Memorial Institute (BMI); Bechtel Hanford, Inc.(BHI); Fluor Hanford, Inc. (FHI); and the Hanford **Environmental Health** Foundation (HEHF). The DOE-Office of River Protection (ORP), responsible for overseeing hazardous waste tank farm clean up along the Columbia

River, is managed by prime contractors CH2M Hill Hanford Group, Inc. (CHG) and Bechtel National, Inc. (BNI).

Over the period from 1943 to 1963, a total of nine plutonium-production reactors and five processing centers were built at Hanford, with the last of the reactors ceasing operations in 1987 (permanent shut-down of the Fast Flux Test Facility [FFTF], a sodium-cooled breeding reactor that produced isotopes for medical and industrial use, was ordered to close in 2001). Plutonium produced at Hanford was used in the world's first atomic explosion at Alamogordo, New Mexico in 1945. The Hanford Site processed an estimated 74 tons of plutonium during its years of active operation, accounting for approximately two-thirds of all plutonium produced for United States military use.

The plutonium fuel was processed on site at the Plutonium and **Uranium** Extraction Plant (PUREX). In the processing of plutonium, a substantial quantity of **radioactive waste** is produced; at Hanford, it amounts to 40% of the nation's one billion Curies of **high-level radioactive waste** from weapons production. PUREX ceased regular production in 1988 and was officially closed in 1992. Deactivation of the plant was completed in 1997.

During the HEWs operational lifetime, some high-level radioactive wastes were diverted from the relatively safe underground storage to surface trenches. Lower-level contaminated water was also released into ditches and the nearby Columbia River. The DOE reports that over 450 billion gallons of waste liquid from the Hanford plants was improperly discharged into the **soil** column during their operational lifetime. These wastes contained cesium-137, technetium-99, plutonium-239 and -240, strontium-90, and cobalt-60. So much low-level waste was dumped that the **groundwater** under the reservation was observed to rise by as much as 75 ft (23 m).

Today more than 50 million gal (189.3 million l) of high-level radioactive waste is contained in approximately 177 underground storage tanks, 67 of which have known leaks. One million gallons (3.8 million l) of this tank waste has already leaked into the surrounding ground and groundwater. An estimated 25 million ft^4 of radioactive solid wastes remains buried in trenches which are similar to septic-tank **drainage** fields. Spent nuclear fuel basins have leaked over 15 million gal (56.8 million l) of radioactive waste. In total, over 1,900 waste sites and 500 contaminated facilities have been identified for clean up at Hanford. The contaminated zone encompasses a variety of ecosystems and the nearby Columbia River.

In the early 1990s, Congress passed a bill requiring the DOE to create a watchdog list of those Hanford tanks at risk for explosion or other potential release of high-risk radioactive waste. By 1994, the list had 56 tanks listed as a high-risk potential. By late 2001, the final 24 tanks had been removed from the congressional watch list, which is sometimes referred to as the "Wyden Watch List" (after sponsoring Senator Ron Wyden).

In 1989, the DOE, U.S. **Environmental Protection Agency** (EPA), and the State of Washington Department of Ecology signed the Hanford Federal Facility Agreement and Consent Order ("Tri-Party Agreement"). The Tri-Party Agreement (TPA) outlines cleanup efforts required to achieve compliance with the Comprehensive Environmental Response Compensation and Liability Act (CERCLA; or Superfund) and the **Resource Conservation and Recovery Act** (RCRA).

Compliance with federal and state authorities under the TPA has not always progressed without problems for Hanford officials. The EPA fined DOE for poor **waste management** practices in 1999, levying $367,078 in civil penalties that were later reduced to $25,000 and a promise to spend $90,000 on additional clean-up activities. The following year EPA issued an additional $55,000 fine against the DOE for non-compliance with the Tri-Party agreement. However, the five-year review of the project completed by EPA in 2001, while specifying 18 "action items" for DOE compliance, also states that cleanup of soil waste sites and burial grounds "are proceeding in a protective and effective manner." In March 2002, DOE was fined $305,000 by the Washington Department of Ecology for failing to start construction of a waste treatment facility as outlined in the Tri-Party agreement. As of May 2002, the State had agreed to forgive the fine if the DOE began construction on the facility by the end of the year.

Even though the Hanford site poses significant environmental concerns, the facility has generated a number of innovative technological advances in the clean up and immobilization of radioactive wastes. For instance, one process developed in Hanford's Pacific Northwest Laboratory is *in situ vitrification*, which uses electricity to treat waste and surrounding **contaminated soil**, melting it into a glass material that is more easily disposed. The William R. Wiley Environmental and Molecular Sciences Laboratory (EMSL), which opened in 1997, houses a wide range of experimental programs aimed at solving nuclear waste treatment issues.

And despite the extent of its contamination, the isolation and security of the Hanford site has made the area home to a large and diverse population of **flora** and **fauna**. A 1997 Nature Conservancy study at Hanford found dozens of previously undiscovered and rare plant and animal **species** in various site habitats. The **biodiversity** study led to the establishment of the federally-protected 195,000-acre (79,000-ha) Hanford Reach National Monument in June 2000.

In May 2002 Department of Energy officials introduced a "Performance Management Plan for the Accelerated Cleanup of the Hanford Site." The new plan sets significantly revised goals for the completion of the site cleanup, setting some projects ahead 35 years or more. While the plan was still in its draft stage at the writing of this entry, DOE officials anticipate its approval by the end of 2002. Strategic initiatives outlined in the plan include restoration of the Columbia River Corridor by 2012 and completion of tank decontamination and closure by 2035.

Dr. Garrett Hardin (1915 –)

American environmentalist and writer

Trained as a biologist (University of Chicago undergraduate degree; Ph.D. from Stanford in 1942 in microbial **ecology**) Garrett Hardin spent most of his career at the University of California at Santa Barbara, where his title was Professor of **Human Ecology**. He was born in Dallas, Texas, and grew up in various places in the Midwest, spending summers on his grandparents' farm in Missouri.

Very few biologists, short of Charles Darwin, have generated the levels of controversy that Hardin's thinking and writing have. The controversies, which continue today, center on two metaphors of human-ecological relationships; "the tragedy of the commons" and "the lifeboat ethic."

Hardin is widely credited with inventing the idea of the **tragedy of the commons**, but his work was long preceded by an ancient rhyme about the tragedy that results from stealing the commons from the goose. He did popularize the idea, though, and it made him a force to reckon with in population studies. Seldom is an academic author so identified with one article (though his thoughts on lifeboat ethics have since become almost equal in identification and impact). The idea is very simple: resources held in common will be exploited by individuals for personal gain in disregard of public impacts; individual profit belongs to individual exploiters while they bear the brunt of only part of the impacts. Much of the controversy centers on Hardin's solutions to the tragedy: first, that private property owners "recognize their responsibility to care for" the land, thus lending at least implicit support to privatization efforts and second, the paradoxical idea that since exercise of individual freedom leads to ruin, such freedom cannot be tolerated, thus we must turn to "mutual coercion mutually agreed upon." As Hardin noted, "if everyone would restrain himself, all would be well; but it takes only one less than everyone to ruin a system of voluntary restraint. In a crowded world of less than perfect human beings, mutual ruin is inevitable if there are no controls. This is the tragedy of the commons." Hardin has since expanded on his thesis, answering his critics by incorporating the differences between an open access system and an closed one. But the debate continues.

His other widely debated metaphor was of a lifeboat (standing for a nation's land and resources) occupied by rich people in an ocean of poor people (who have fallen out of their own, inadequate lifeboats). If the rich boat is close to its margin of safety, what should its occupants do about the poor people in the ocean? Or in the other boats? If the occupants let in even a few more people, the boat may be swamped, thus creating an ethical dilemma for the rich occupants. How do these occupants of the already full lifeboat justify taking in additional people if it guarantees the collapse for all? Ever since, Hardin has been accused of social Darwinism, of racism, of ignoring the possibility that "the poverty of the poor may be caused in part by the affluence of the rich," and of isolationism (since he argued that "for the foreseeable future survival demands that we govern our actions by the ethics of a [sovereign] lifeboat" rather than "space-ship" ethics that [arguably] try to care for all equitably).

What Hardin was trying to do in both of these cases was to look unemotionally at **population growth** and resource use, employing the rationale and language of a scientist viewing human populations in an objective, evolutionary perspective. Biologists know that "natural" populations that overuse their resources, that exceed the **carrying capacity** of their range, are then adjusted—in numbers or in resource use levels—also naturally and often brutally (from the perspective of many people). The problems remain that the

division between the rich and the poor in the world is widening, and that many resources and ecosystems on earth are being stressed, though how close to the breaking point no one really knows. Also, nation-states are arbitrary divisions, and perhaps—in a corollary to the space-ship metaphor—the ultimate life-boat is the earth and all the inhabitants must exist in it together.

Hardin retired as a professor emeritus of human ecology, a rare title that reflects his attempts to fold the human **species** into the evolutionary ecology perspective developed in biology. Ultimately what he tried to get across was what he called an *ecolate* view: *ecolacy* asks the question "and then what?" The basic insight of the ecolate citizen is that the world is a complex of systems so intricately interconnected that we can seldom be very confident that a proposed intervention in this system of systems will produce the consequences we want." Hardin's views are rich and varied—the themes presented here are only two of many—but he still summarizes the human condition by what he labels "the ecolate predicament": that all human interventions are doomed to failure if a population exceeds its carrying capacity, whether of a region or of the world. Doing so "will bring everyone down to a level of poverty."

Hawaiian Islands

The Hawaiian Islands are made up of a chain of ancient volcanic islands that have formed at irregular intervals over the last ten million years. There are over 100 islands in the chain, eight of which are considered major. Of the eight major islands, Kauai is the oldest, and the island of Hawaii is the youngest, having formed within the past million years. This vast discrepancy in age has contributed to the tremendous **biodiversity** that has evolved there. The other factor responsible for Hawaii's great **species** diversity is the island chain's remoteness. The nearest continent is 2,400 mi (3,862 km) away, thus limiting the total colonization that could, or has, taken place. The niches available to these colonizing species are very diverse due to geophysical events. For example, on the island of Kauai, the average annual rainfall on the windward side of Mount Waialeale is 460 in (1,169 cm), whereas on its leeward side, it is only 19 in (48 cm). The temperature on the islands ranges from 75–90°F (24–32°C) for 300 days each year. The lowest temperature ever recorded in Hawaii was 54°F (12°C). Thus with its tropical **climate** and unique biotic communities, it is easy to understand why Hawaii has been considered a paradise. But now this paradise is threatened by serious environmental problems caused by humans.

The impact of humans has been felt in the Hawaiian Islands since their first arrival, but perhaps never more so than today. In the last quarter century tourism has replaced sugar cane and pineapple as the islands' main revenue source. Over six million tourists visit Hawaii each year spend $11 million a day. With tourism comes development that often destroys natural habitats and strains existing **natural resources**. Hawaii has more than 60 **golf courses**, with plans to develop at least 100 more. This would destroy thousands of acres of natural vegetation, require the use of millions of gallons of freshwater for **irrigation**, and necessitate the use of tons of chemical fertilizers and pesticides in their maintenance. The increased number of tourists, many of whom visit the islands to enjoy its natural beauty, are often destroying the very thing they are there to see. Along the shore of Hanauma Bay, just south of Honolulu, over 90% of the **coral reef** is dead, primarily because people have trampled it in their desire to see and experience this unique piece of **nature**.

Much of Hawaii's **fauna** and **flora** are unique. Over 10,000 species are native to the Hawaiian Islands, having evolved and filled specialized niches there through the process of adaptive radiation from the relatively few original colonizing species. Examples are found in virtually every group of plants and animals in Hawaii. The avian adaptive radiation in the Hawaiian Islands surpasses even the best-known example, Darwin's finches of the Galapagos Islands. From as few as 15 colonizing species evolved 90 native species of birds in the Hawaiian archipelago. Included in this number are the Hawaiian honeycreepers of the family Drepanididae. This endemic family of birds arose from a single ancestral species, which gave rise to 23 species, including 24 subspecies, of honeycreepers spread throughout the main islands. **Niche** availability and reproductive isolation contributed greatly to the spectacular diversity of forms that evolved. These birds developed adaptations such as finch-like bills for crushing seeds, parrot-like bills for foraging on

larvae in wood, long decurved bills for taking nectar and insects from specialized flowers, and small forcep-like bills for capturing insects.

Introductions of vast numbers of alien species is taking its toll on native Hawaiian species, a process that began when the first humans settled the islands over 1,500 years ago. Many native species of birds had experienced drastic population declines by the time Europeans first encountered the islands over 200 years ago. Since then at least 23 species of Hawaii's native birdlife have become extinct, and currently over 30 additional avian species are threatened with **extinction**. Through the process of primary ecological **succession**, one new species became established in the Hawaiian Islands every 70,000 years. Introductions of alien species are taking place a million times faster, and are thus eliminating native species at an unprecedented rate. Recent estimates indicate that there are over 8,000 **introduced species** of plants and animals throughout the Hawaiian Island chain. The original Polynesian settlers brought with them pigs, dogs, chickens, and rats, along with a variety of plants they had cultivated for fiber, food, and medicine. With the Europeans came cattle, horses, sheep, cats, and additional rodents. The mongoose was introduced purposefully to control the rat populations; however, they presented more of a threat to ground-nesting birds. The introduction of rabbits caused the loss of vast quantities of vegetation and ultimately the extinction of three bird species on Laysan Island. Over 150 species of birds, including escaped cage birds, have been introduced to the islands. However, most of these have not established breeding populations.

Although Hawaii represents only 0.2% of the United States's land base, almost 75% of the total extinctions of birds and plants of the nation have occurred in this state. Hawaii's endemic flora are disappearing rapidly. Introduced mammalian browsers are decimating the native plantlife, which never needed to evolve defense mechanisms against such predators, and other introduced animals are destroying populations of native pollinators. **Habitat** destruction and opportunistic non-native vegetation are also working against the endemic Hawaiian plant species. Organizations such as the Hawaii Plant Conservation Center are working to preserve the state's floral diversity by collecting and propagating as many of the rare and **endangered species** as possible. Their greenhouses now contain over 2,000 plants representing almost two thirds of Hawaii's native species, and their goal is to propagate 400 of the state's most endangered plants.

Introduced plant and animal species and their assault on native species are by no means the only environmental problems facing the Hawaiian Islands. Because Hawaii's population is growing at a higher rate than the national average, and in part due to its isolation, it is facing many environmental problems on a grander scale and at a more rapid rate than its sister states on the mainland. Energy is one of the primary problems. Much of Hawaii's electricity is produced by burning imported oil, which is extremely expensive. Because of limited reserve capabilities with regard to electrical generation, Hawaii faces the potential for blackouts.

Planners have been, over the past several decades, looking at the feasibility of tapping into Hawaii's seemingly vast **geothermal energy** resources. Hawaii has the most active **volcano** in the world, Kilauea, whose underground network of geothermal reserves is the largest in the state. The proposed Hawaii Geothermal Deep Water Cable project would supply the energy for a 500-megawatt power plant, the electrical power of which would be transmitted from the island of Hawaii to Oahu by three undersea cables. This would, of, course, be of economic and environmental benefit by reducing dependence on oil reserves. Opponents of this geothermal power plant point to several problems. They are concerned with the potential for the release of toxic substances, such as **hydrogen** sulfide, **lead**, **mercury**, and chromium, into the **environment** from well-heads. They also have voiced negative opinions concerning construction of a geothermal plant so near the lava flows and fissures of Hawaii's two active volcanoes. An alternately proposed site would have the facility located in Hawaii's last major inholding of lowland **tropical rain forest**. To avoid economic disaster from escalating prices for imported oil and the problem of frequent blackouts, Hawaii must reach some compromise on geothermal energy and/or research the potential for getting its electricity from one or more of wind, wave, or **solar energy**.

Hawaii is also faced with environmental problems of another sort–natural disasters. Volcanoes not only provide the potential for geothermal energy, they also have the potential for massive destruction. Over the past 200 years, Hawaii's two active volcanoes, Kilauea and Mauna Loa, have covered nearly 200,000 acres (81,000 ha) of land with lava, and geologists expect them to remain active for centuries to come. Severe hurricanes and tidal waves also hold the potential for vast destruction, not only of human property and lives, but of natural areas and the **wildlife** it holds. Many of the **endemic species** of Hawaii are threatened or endangered, and their populations are often so low that a single storm could wipe out most or all of its numbers.

There are efforts to reverse the environmental destruction in the Hawaiian Islands. Several organizations comprised of native Hawaiians are working to stem the destruction and loss of the **wilderness** paradise discovered by their ancestors.

Denis Allen Hayes (1944 –)

American environmental activist and Earth Day organizer

As executive director of the first **Earth Day** in April 1970, Hayes helped launch the modern movement of **environmentalism**, and has promoted the use of **solar energy** and other renewable resources. A native of Camas, Washington, Hayes acquired his appreciation of **nature** exploring and enjoying the mountains, lakes, and beaches of the Pacific Northwest. At age 19, he dropped out of Clark College in Vancouver, Washington, and spent the next three years traveling the world. He installed church pews in Honolulu, taught swimming and modeled in Tokyo, and hitchhiked through Africa.

After returning to the United States, Hayes enrolled at Stanford as a history major, was elected student body president, and became active in the anti-Viet Nam War movement, occupying laboratories that researched military projects. After graduating from Stanford, he went to Harvard Law School, but dropped out in 1970 to help organize the first Earth Day. During the Carter administration, Hayes headed the federal Solar Energy Research Institute. He left after the agency's $120 million budget was cut by the Reagan administration. From 1983 to 1992, after completing his law degree at Stanford, he served there as an adjunct professor of engineering.

In 1990, as the international chairman of Earth Day on its twentieth anniversary, Hayes helped to organize participation by over 200 million people in 141 countries. This event generated extraordinary publicity for and concern about global environmental problems. In 1992, Hayes was named president of the Seattle-based Bullitt Foundation, which works to protect the **environment** of the Pacific Northwest and to help disadvantaged children. He also serves as chairman of the board of **Green Seal**, a group that endorses consumer products meeting strict environmental standards and co-chairs the group promoting the "Valdez Principles" of corporate responsibility.

Denis Hayes. (Corbis-Bettmann. Reproduced by permission.)

Hayes has received awards and honors from many groups, including the **Humane Society of the United States**, the Interfaith Center for Corporate responsibility, the **National Wildlife Federation**, and the **Sierra Club**. In 1990, *Life* magazine named him one of the 18 Americans most likely to have an impact on the twenty-first century.

Hayes has written over 100 papers and articles, and his book on solar energy, *Rays of Hope: The Transition to a Post-Petroleum World*, has been published in six languages. He has long advocated increased development of solar and other **renewable energy** sources, which he believes could provide most of the nation's energy supply within a few years.

In 1990, Hayes wrote that "Time is running out. We have at most ten years to embark on some undertakings if we are to avoid crossing some dire environmental thresholds. Individually, each of us can do only a little. Together, we can save the world."

Hazard ranking system

The Hazard ranking system (HRS) is a numerical scoring procedure that the federal **Environmental Protection Agency** (EPA) uses to place and prioritize waste sites on the **National Priorities List**. Only these priority sites can be cleaned up through the Superfund Trust Fund program.

The HRS score is based on an evaluation of threats related to the release or potential release of hazardous substances. The HRS assessment of a site ranks public health factors such as threats to drinking water, the food chain, and populations exposed through occupational and ambient environments. Also evaluated are environmental threats like the effect of substances on **air quality**, resources, and sensitive ecosystems.

Federal investigators score a site by evaluating four pathways that could be affected by hazardous releases. The pathways are ground water **migration**, surface water migration, air migration, and **soil** exposure.

The pathway scores are combined using a root-mean-square equation. This calculation produces the overall score for a site. A high HRS score does not guarantee immediate action because clean-up work may be going on at other sites. The decision to take action on a site is based on additional research that includes a remedial investigation of what corrective action is needed.

Hazardous chemicals

see **Hazardous material; Hazardous waste**

Hazardous material

Any agent that presents a risk to life-forms or the **environment** can be considered a hazardous material. This is a very broad term which encompasses pure compounds and mixtures, raw materials, and other naturally occurring substances, as well as industrial products and wastes. Depending on the nature and the length of exposure, virtually all substances can have toxic effects, ranging from headaches and dizziness to **cancer**. The challenge facing any legislation is not only to devise regulations for the safe handling of hazardous materials but also to define the term itself.

The legislation that offers the most detailed and comprehensive definition of hazardous materials is the **Resource Conservation and Recovery Act** (RCRA), enacted in 1976. RCRA classifies a waste mixture or compound as hazardous if it fails what is called a *characteristic test* or appears on one of a few lists. The lists of hazardous wastes include those from specific and nonspecific sources and those which are acutely hazardous and generally hazardous. There are four characteristic tests: ignitability, reactivity, corrosivity, and extraction-procedure toxicity.

A waste fails the ignitable test if it is a liquid with flash point below 140°F (60°C); or a solid that, under standard temperature and pressure, causes fire through friction, absorbing moisture, or spontaneous changes and burns vigorously and persistently; or a compressed gas defined by the Department of **Transportation** (DOT) as an oxidizer or as being ignitable. Spent solvents, paint removers, epoxy resins, and waste inks are often classified as hazardous under this definition.

A waste fails the corrosivity test if it is aqueous and has a **pH** of either 2 or less or 12.5 or more, or if it is a liquid that corrodes steel at a rate equal to or more than 0.25 in (6.35 mm) per year. Examples of corrosive wastes include various acids and bases such as nitric **acid**, ammonium hydroxide, perchloric acid, sulfuric acid, and sodium hydroxide, though a waste will not be classified as hazardous in this test if these acids and bases are neutralized or present at low levels.

Reactivity is related to one of the following criteria: If the material is unstable, with the potential for violent reactions with water, or generates toxic fumes; if it has cyanide and sulfide content; if it can be easily detonated; or is defined by DOT as a Class A or B explosive. Compounds commonly causing wastes to fall into this category are chromic acid, hypochlorites, picric acid, nitroglycerin, dinitrophenol, and organic peroxides.

Extraction-Procedure toxicity is determined through the extraction of **solid waste**, in a procedure referred to as the *Toxicity Characteristic Leaching Procedure* (TCLP). Liquid waste can also fail this test, although a liquid containing less than 0.5% solids after **filtration** does not need to undergo it. Such a liquid can be directly analyzed for contaminants. In the TCLP, solids are extracted in a mildly acidic medium (pH 5.0) for 18 hours using a tumbling apparatus, and the

resulting liquid extract is then analyzed for contaminants. The waste is deemed to be hazardous if the level of a contaminant detected in this extraction procedure exceeds a given level. If liquid extracts contain **arsenic** at a concentration greater than 5.0 mg/l, for example, the waste is classified as hazardous. Different methods are recommended by the **Environmental Protection Agency** (EPA) for measuring the contaminants in each class.

The Resource Conservation and Recovery Act (1976) and the Hazardous and Solid Waste Amendments added to it in 1984 were intended to protect **groundwater**, surface water, and land from improper management of solid wastes. The act and the amendments defined the responsibilities of industries and others who generate and transport **hazardous waste**. They also set standards for land disposal facilities and underground storage tanks, as well as standards for proper management of hazardous materials from "cradle to grave."

The Toxic Substances Control Act (1976) is another important piece of legislation concerning hazardous materials. It was intended to regulate the introduction and use of new, potentially hazardous substances. The bill requires industry to test extensively **chemicals** that may be harmful, and it requires industries to provide the EPA with information about the production, use, and health effects of any new substances or mixtures before they are manufactured.

The Comprehensive Environmental Response, Compensation and Liabilities Act (CERCLA) (1980) and the Superfund Amendments and Reauthorization Act (SARA) (1986) set policy for situations in which hazardous materials have been mismanaged in the past. These legislations have established a system for ranking sites that need **remediation**, called the **Hazard Ranking System**, as well as a procedure for raising funds to support these efforts. The bills also impose schedules for site investigations, feasibility studies, and remedial action.

The definition of hazardous materials remains a difficult and complex issue. There are changes in public perceptions about certain materials, such as **asbestos** or **lead**, and there are scientific contributions which result in the addition or deletion of various chemicals or compounds from lists of hazardous materials. The definition is therefore dynamic, but changes are made within a regulatory framework designed to protect both life and the environment.

Hazardous materials, storage and transport

see **Storage and transport of hazardous material**

Hazardous Materials Transportation Act (1975)

The Hazardous Materials **Transportation** Act, enacted in 1975 as part of a law dealing with transportation safety, strengthened the 1970 Hazardous Materials Transportation Control Act. The impetus for this act was increased illegal, or midnight, dumping; increasing spills; and poor enforcement. Illegal dumping increased in the 1970s as many landfills began to refuse to take **hazardous waste**, thus dramatically increasing the costs of disposal. The illegal dumping took place in vacant lots, along highways, or actually on the highways. In the congressional debate on the act, the U.S. Department of Transportation (DOT), which administers the law, estimated that 75% of all hazardous waste shipments violated the existing regulations. This poor enforcement was due to a lack of inspection personnel, fragmented jurisdiction and lack of coordination among the Coast Guard, the Federal Aviation Administration, the Federal Highway Administration, and the Federal Railroad Administration.

The law establishes minimum standards of regulation for the transport of hazardous materials by air, ship, rail, and motor vehicle. The DOT regulates the packing, labeling, handling, vehicle routing, and manufacture of packing and transport containers for hazardous materials transportation. The hazardous materials and wastes covered by the law, based on DOT regulations, are those on the **Resource Conservation and Recovery Act** (RCRA) list and certain substances designated by the **Environmental Protection Agency** under the authority of Superfund. All hazardous waste transporters must register as such with the proper state and federal agencies; they must use the RCRA uniform manifest system to track the pick-up and delivery of all shipments; they must only deliver to permitted hazardous waste facilities; they must notify the proper agencies of any accidents; they must clean up any discharges that occur

during the transportation process. The law also provides a significant role for the states, though there are provisions in the act to prevent overly strict state and local regulations of hazardous waste transport. The Hazardous Materials Transportation Act includes numerous information requirements, also designed to increase public safety. Each vehicle carrying hazardous materials must display a sign identifying the hazard class of the cargo, and emergency response information has been required since 1990. Each shipment must also be accompanied by its RCRA hazardous waste manifest.

The manifest system is part of the RCRA "cradle-to-grave" approach to regulating hazardous materials. The system is supposed to prevent illegal dumping, since hazardous waste transporters could not accept hazardous waste without a manifest, and, similarly, hazardous waste treatment and disposal facilities could not accept waste from transporters without a manifest. Since all hazardous materials could be traced and accounted for through such manifests, illegal dumping should stop. Nevertheless, it is unclear how much effect the manifest system has had on illegal dumping since such dumping is still less costly than proper disposal.

In 1990, the Hazardous Materials Transportation Uniform Safety Act was passed, the first major amendments to the 1975 Act. Poor enforcement of the existing law was the stimulus for action. The law focused on better enforcement by increasing the number of inspectors, increasing the civil and criminal penalties for violation of the regulations, and helping states better respond to accidents involving hazardous materials. *See also* Chemical spills; Comprehensive Environmental Response, Compensation and Liability Act (CERLA) (1980); Hazardous waste siting; Solidification of hazardous material; Storage and transport of hazardous materials

Hazardous Substances Act (1960)

This law was one of Congress's first forays into consumer protection, and it helped to pave the way for the explosion in consumer protection legislation that began in the mid-1960s. The Hazardous Substances Labeling Act was passed in 1960 (the word "Labeling" was deleted by the 1966 amendments the act). The law authorized the Secretary of the Department of Health, Education, and Welfare (HEW) to require warning labels for household substances that were deemed hazardous. These substances were categorized as: toxic, corrosive, irritant, strong sensitizer, flammable or combustible, pressure generating, or radioactive. The law does not cover pesticides (which are regulated by the Federal Insecticide, **Fungicide**, and Rodenticide Act); food, drugs, or cosmetics (which are covered by the Federal Food, Drug, and Cosmetics Act); radioactive materials related to **nuclear power**; fuels for cooking, heating, or refrigeration; or **tobacco** products.

A product is defined to be hazardous if it might lead to personal injury or substantial illness, especially if there is a reasonable danger that a child might ingest the substance. When the HEW Secretary declares a substance to be hazardous, a label is required. The label must include a description of the chief hazard and first aid instructions, along with handling and storage instructions. If its chief hazard is flammable, corrosive, or toxic, it must say DANGER on the label; other hazardous substances require either CAUTION or WARNING. In addition, all labels must include the statement "Keep out of the reach of children."

Major amendments to the act, the Child Protection Act, were passed in 1966. These amendments, largely in response to the message on consumer issues by President Lyndon Johnson, expanded federal control over hazardous substances. The **Food and Drug Administration** (FDA), which administered the law, could now ban substances (after formal hearings) that were deemed too hazardous, even if they had a warning label, if "the degree or **nature** of the hazard involved in the presence or use of such substance in households is such that the objective of the protection the public health and safety can be adequately served" only by such a ban. The amendments also extended the scope of the law to pay greater attention to toys and children's articles. This meant the government could require a warning on all household items, rather than just packaged items.

The Child Protection and Toy Safety Act of 1969 further amended the Hazardous Substances Act. Toys could be declared hazardous if they presented electrical, mechanical, or thermal dangers. Also, substances that were hazardous to children, including toys, could be banned automatically. As the titles of these amendments suggest, the Hazardous Substances Act became the primary vehicle to protect children from dangerous substances and toys. Administration of the act has been shifted to the Consumer Product Safety Commission. If the Commission finds a "substantial risk of injury," children's clothes, furniture, and toys can be pulled from the market immediately. *See also* Environmental law; Hazardous

material; Hazardous Materials Transportation Act; Hazardous waste; Hazardous waste siting; Radioactive waste; Radioactivity

Hazardous waste

Of the thousands of millions of tons of waste generated in the United States annually, approximately 60 million tons are classified as hazardous. Hazardous waste is legally defined by the **Resource Conservation and Recovery Act** (RCRA) of 1976. The RCRA defines hazardous waste as any waste or combination of wastes, which because of its quantity, concentration, or physical, chemical, or infectious characteristics may: A) cause, or significantly contribute to, an increase in **mortality** or an increase in serious irreversible or incapacitating illness; or, B) pose a substantial present or potential hazard to human health or the **environment** when improperly treated, stored, transported, disposed of, or otherwise managed.

In the Code of Federal Regulations, the **Environmental Protection Agency** (EPA) specifies that a **solid waste** is hazardous if it meets any of four conditions: 1) It exhibits ignitability corrosivity, reactivity, or EP toxicity; 2) has been listed as a hazardous waste; 3) is a mixture containing a listed hazardous waste and a nonhazardous waste, unless the mixture is specifically excluded or no longer exhibits any of the four characteristics of hazardous waste; 4) is not specifically excluded from regulation as a hazardous waste.

The EPA established two criteria for selecting the characteristics given above. The first criterion is that the characteristic is capable of being defined in terms of physical, chemical, or other properties. The second criterion is that the properties defining the characteristic must be measurable by standardized and available test procedures. For example under the term ignitability (Hazard code label "I"), any one of four criteria can be met: 1) A liquid with a flash point less than 60°F (16°C); 2) If not a liquid, then it is capable under standard temperature and pressure of causing fire through friction, **absorption** of moisture, or spontaneous chemical changes, and when ignited, burns so vigorously and persistently that it creates a hazard; 3) It may be an ignitable compressed gas; 4) It is an oxidizer.

Similarly under the characteristics of corrosivity, reactivity, and toxicity, there are specifically defined requirements which are spelled out in the Code of Federal Register (CFR). Further examples are given below:

Corrosivity (Hazard code "C") has either of the following properties: an aqueous waste with a **pH** equal to or less than 2.0 or greater than 12.5; or a liquid which will corrode **carbon** steel at a rate greater than 0.25 in (0.64 cm) per year.

Reactivity (Hazard code "R") has at least one of the following properties: a substance which is normally unstable and undergoes violent physical and/or chemical change without being detonated; a substance which reacts violently with water (for example, sodium metal); a substance which forms a potentially explosive mixture when mixed with water; a substance which can generate harmful gases, vapors, or fumes when mixed with water; a cyanide- or sulfide-bearing waste which can generate harmful gases, vapors, or fumes when exposed to pH conditions between 2 and 12.5; a waste which, when subjected to a strong initiating source or when heated in confinement, will detonate and/or generate an explosive reaction; a substance which is readily capable of detonation at standard temperature and pressure.

Toxicity (Hazard code "E") has the properties such that an aqueous extract contains contamination in excess of that allowed (e.g., **arsenic** >5 mg/l; barium 0.100 mg/l; **cadmium** >1 mg/l; chromium >5 mg/l; **lead** >5 mg/l). Additional codes under toxicity include an "acute hazardous waste" with code "H": a substance which has been found to be fatal to humans in low doses or has been found to be fatal in corresponding human concentrations in laboratory animals. Toxic waste (hazard code "T") designates wastes which have been found through laboratory studies to be a **carcinogen**, **mutagen**, or **teratogen** for humans or other life forms.

Certain wastes are specifically excluded from classification as hazardous wastes under RCRA, including domestic sewage, **irrigation** return flows, **household waste**, and nuclear waste. The latter is controlled via other legislation. The impetus for this effort at legislation and classification comes from several notable cases such as **Love Canal**, New York; **Bhopal, India**; **Stringfellow Acid Pits** (Glen Avon, California); and **Seveso, Italy**; which have brought media and public attention to the need for identification and classification of dangerous substances, their effects on health and the environment, and the importance of having knowledge about the potential risk associated with various wastes.

A notable feature of the legislation is its attempt at defining terms so that professionals in the field and government officials will share the same vocabulary. For example, the difference between "toxic" and "hazardous" has been established; the former denotes the capacity of a substance to produce injury and the latter denotes the *probability* that injury will result from the use of (or contact with) a substance.

The RCRA legislation on hazardous waste is targeted toward larger generators of hazardous waste rather than small operations. The small generator is one who generates less than 2,205 lb (1,000 kg) per month; accumulates less than

2,205 lb (1,000 kg); produces wastes which contain no more than 2.2 lb (1 kg) of acutely hazardous waste; has containers no larger than 5.3 gal (20 l) or contained in liners less than 22 lb (10 kg) of weight of acutely hazardous waste; has no greater than 220 lb (100 kg) of residue or **soil** contaminated from a spill, etc. The purpose of this exclusion is to enable the system of regulations to concentrate on the most egregious and sizeable of the entities that contribute to hazardous waste and thus provide the public with the maximum protection within the resources of the regulatory and legal systems.

Hazardous waste site remediation

The overall objective in remediating **hazardous waste** sites is the protection of human health and the **environment** by reducing risk. There are three primary approaches which can be used in site **remediation** to achieve acceptable levels of risk:

- the hazardous waste at a site can be contained to preclude additional **migration** and exposure
- the hazardous constituents can be removed from the site to make them more amenable to subsequent ex situ treatment, whether in the form of **detoxification** or destruction
- the hazardous waste can be treated in situ (in place) to destroy or otherwise detoxify the hazardous constituents

Each of these approaches has positive and negative ramifications. Combinations of the three principal approaches may be used to address the various problems at a site. There is a growing menu of technologies available to implement each of these remedial approaches. Given the complexity of many of the sites, it is not uncommon to have treatment trains with a sequential implementation of various in situ and/or ex situ technologies to remediate a site.

Hazardous waste site remediation usually addresses soils and **groundwater**. However, it can also include wastes, surface water, **sediment**, sludges, bedrock, buildings, and other man-made items. The hazardous constituents may be organic, inorganic and, occasionally, radioactive. They may be elemental ionic, dissolved, sorbed, liquid, gaseous, vaporous, solid, or any combination of these.

Hazardous waste sites may be identified, evaluated, and if necessary, remediated by their owners on a voluntary basis to reduce environmental and health effects or to limit prospective liability. However, in the United States, there are two far-reaching federal laws which may mandate entry into the remediation process: the **Comprehensive Environmental Response, Compensation, and Liability Act** (CERCLA, also called the Superfund law), and the **Resource Conservation and Recovery Act** (RCRA). In addition, many of the states have their own programs concerning abandoned and uncontrolled sites, and there are other laws that involve hazardous site remediation, such as the clean-up of polychlorinated biphenyl (PCB) under the auspices of the federal Toxic Substances Control Act (TSCA).

Potential sites may be identified by their owners, by regulatory agencies, or by the public in some cases. Site evaluation is usually a complicated and lengthy process. In the federal Superfund program, sites at which there has been a release of one or more hazardous substances that might result in a present or potential future threat to human health and/or the environment are first evaluated by a Preliminary Assessment/Site Inspection (PA/SI). The data collected at this stage is evaluated, and a recommendation for further action may be formulated. The **Hazard Ranking System** (HRS) of the U.S. **Environmental Protection Agency** (EPA) may be employed to score the site with respect to the potential hazards it may pose and to see if it is worthy of inclusion on the **National Priorities List** (NPL) of sites most deserving the attention of resources.

Regardless of the HRS score or NPL status, the EPA may require the parties responsible for the release (including the present property owner) to conduct a further assessment, in the form of the two-phase Remedial Investigation/Feasibility Study (RI/FS). The objective of the RI is to determine the nature and extent of contamination at and near the site. The RI data is next considered in a baseline **risk assessment**. The risk assessment evaluates the potential threats to human health and the environment in the absence of any remedial action, considering both present and future conditions. Both exposure and toxicity are considered at this stage.

The baseline risk assessment may support a decision of no action at a site. If remedial actions are warranted, the second phase of the RI/FS, an engineering Feasibility Study, is performed to allow for educated selection of an appropriate remedy. The final alternatives are evaluated on the basis of nine criteria in the federal Superfund program. The EPA selects the remedial action it deems to be most appropriate and describes it and the process which led to its selection in the **Record of Decision** (ROD). Public comments are solicited on the proposed clean-up plan before the ROD is

issued. There are also other public comment opportunities during the RI/FS process. Once the ROD is issued, the project moves to the Remedial Design/Remedial Action (RD/RA) phase unless there is a decision of no action. Upon design approval, construction commences. Then, after construction is complete, long-term operation, maintenance, and monitoring activities begin.

For Superfund sites, the EPA may allow one or more of the responsible parties to conduct the RI/FS and RD/RA under its oversight. If possibly responsible parties are not willing to participate or are unable to be involved for technical, legal, or financial reasons, the EPA may choose to conduct the project with government funding and then later seek to recover costs in lawsuits against the parties. Other types of site remediation programs often replicate or approximate the approaches described above. Some states, such as Massachusetts, have very definite programs, while others are less structured.

Containment is one of the available treatment options. There are several reasons for using containment techniques. A primary reason is difficulty in excavating the waste or treating the hazardous constituents in place. This may be caused by construction and other man-made objects located over and in the site. Excavation could also result in uncontrollable releases at concentrations potentially detrimental to the surrounding area. At many sites, the low levels of risks posed, in conjunction with the relative costs of treatment technologies, may result in the selection of a containment remedy.

One means of site containment is the use of an impermeable cap to reduce rainfall **infiltration** and to prevent exposure of the waste through **erosion**. Another means of containment is the use of cut-off walls to restrict or direct the movement of groundwater. In situ solidification can also be used to limit the mobility of contaminants. Selection among alternatives is very site specific and reflects such things as the site **hydrogeology**, the chemical and physical nature of the contamination, proposed **land use**, and so on. Of course, the resultant risk must be acceptable.

As with any in situ approach, there is less control and knowledge of the performance and behavior of the technology than is possible with off-site treatment. Since the use of containment techniques leaves the waste in place, it usually results in long-term monitoring programs to determine if the remediation remains effective. If a containment remedy were to fail, the site could require implementation of another type of technology.

The ex situ treatment of hazardous waste provides the most control over the process and permits the most detailed assessments of its efficacy. Ex situ treatment technologies offer the biggest selection of options, but include an additional risk factor during transport. Examples of treatment options include **incineration**; innovative thermal destruction, such as infrared incineration; **bioremediation**; stabilization/solidification; **soil** washing; chemical extraction; chemical destruction; and thermal desorption. Another approach to categorizing the technologies available for hazardous waste site remediation is based upon their respective levels of demonstration. There are existing technologies, which are fully demonstrated and in routine commercial use. Performance and cost information is available. Examples of existing technologies include **slurry** walls, caps, incineration, and conventional solidification/stabilization.

The next level of technology is innovative and has grown rapidly as the number of sites requiring remediation grew. Innovative technologies are characterized by limited availability of cost and performance data. More site-specific testing is required before an innovative technology can be considered ready for use at a site. Examples of innovative technologies are vacuum extraction, bioremediation, soil washing/flushing, chemical extraction, chemical destruction, and thermal desorption. Vapor extraction and in situ bioremediation are expected to be the next innovative technologies to reach "existing" status as a result of the growing base of cost and performance information generated by their use at many hazardous waste sites.

The last category is that of emerging technologies. These technologies are at a very early stage of development and therefore require additional laboratory and pilot scale testing to demonstrate their technical viability. No cost or performance information is available. An example of an emerging technology is electrokinetic treatment of soils for metals removal.

Groundwater contaminated by hazardous materials is a widespread concern. Most hazardous waste site remediations use a pump and treat approach as a first step. Once the groundwater has been brought to the surface, various treatment alternatives exist, depending upon the constituents present. In situ air sparging of the groundwater using pipes, **wells**, or curtains is also being developed for removal of volatile constituents. The vapor is either treated above ground with technologies for off-gas emissions, or biologically in the unsaturated or **vadose zone** above the **aquifer**. While this approach eliminates the costs and difficulties in treating the relatively large volumes of water (with relatively low contaminant concentrations) generated during pump-and-treat, it does not necessarily speed up remediation.

Contaminated bedrock frequently serves as a source of groundwater or soil recontamination. Constituents with densities greater than water enter the bedrock at fractures, joints or bedding planes. From these locations, the contamination tends to diffuse in all directions. After many years of accumulation, bedrock contamination may account for the majority of the contamination at a site. Currently, little can be done to remediate contaminated bedrock. Specially

designed vapor stripping applications have been proposed when the constituents of concern are volatile. Efforts are on-going in developing means to enhance the fractures of the bedrock and thereby promote removal. In all cases, the ultimate remediation will be driven by the diffusion of contaminants back out of the rock, a very slow process.

The remediation of buildings contaminated with hazardous waste offers several alternatives. Given the cost of disposal of hazardous wastes, the limited disposal space available, and the volume of demolition debris, it is beneficial to determine the extent of contamination of construction materials. This contamination can then be removed through traditional engineering approaches, such as scraping or sand blasting. It is then only this reduced volume of material that requires treatment or disposal as hazardous waste. The remaining building can be reoccupied or disposed of as nonhazardous waste. *See also* Hazardous material; Hazardous waste siting; Solidification of hazardous materials; Vapor recovery system

Hazardous waste siting

Regardless of the specific technologies to be employed, there are many technical and nontechnical considerations to be addressed before **hazardous waste** can be treated or disposed of at a given location. The specific nature and relative importance of these considerations to the successful siting reflect the chemodynamic behavior (i.e., transport and fate of the waste and/or treated residuals in the **environment** after **emission**) as well as the specifics of the location and associated, proximate areas. Examples of these considerations are: the nature of the **soil** and hydrogeological features such as depth to and quality of **groundwater**; quality, use, and proximity of surface waters; and **ambient air** quality and meteorological conditions; and nearby critical environmental areas (**wetlands**, preserves, etc.), if any. Other considerations include surrounding **land use**; proximity of residences and other potentially sensitive receptors such as schools, hospitals, parks, etc.; availability of utilities; and the capacity and quality of the roadway system. It is also critical to develop and obtain the timely approval of all appropriate local, state, and federal permits. Associated with these permits is the required documentation of financial viability as established by escrowed closure funds, site insurance, etc. Site-specific standard operating procedures as well as contingency plans for use in emergencies are also required. Additionally, there needs to be baseline and ongoing monitoring plans developed and implemented to determine if there are any releases to or general degradation of the environment. One should also anticipate public hearings before permits are granted. Several states in the United States have specific regulations which restrict the siting of hazardous **waste management** facilities.

Haze

An **aerosol** in the **atmosphere** of sufficient concentration and extent to decrease **visibility** significantly when the relative humidity is below saturation is known as haze. Haze may contain dry particles or droplets or a mixture of both, depending on the precise value of the humidity. In the use of the word, there is a connotation of some degree of permanence. For example, a dust storm is not a haze, but the coarse particles may settle rapidly and leave a haze behind once the velocity drops.

Human activity is responsible for many hazes. Enhanced **emission** of **sulfur dioxide** results in the formation of aerosols of sulfuric **acid**. In the presence of ammonia, which is excreted by most higher animals including humans, such emissions result in aerosols of ammonium sulfate and bisulfate. Organic hazes are part of **photochemical smog**, such as the **smog** often associated with Los Angeles, and they consist primarily of polyfunctional, highly oxygenated compounds with at least five **carbon** atoms. Such hazes can also form if air with an enhanced **nitrogen** oxide content meets air containing the natural terpenes emitted by vegetation.

All hazes, however, are not products of human activity. Natural hazes can result from forest fires, dust storms, and the natural processes that convert gaseous contaminants into particles for subsequent removal by precipitation or deposi-

tion to the surface or to vegetation. Still other hazes are of mixed origin, as noted above, and an event such as a dust storm can be enhanced by human-caused devegetation of **soil**.

Though it may contain particles injurious to health, haze is not of itself a health hazard. It can have a significant economic impact, however, when tourists cannot see scenic views, or if it becomes sufficiently dense to inhibit aircraft operations. *See also* Air pollution; Air quality; Air quality criteria; Los Angeles Basin; Mexico City, Mexico

Heat (stress) index

The heat index (HI) or heat stress index—sometimes called the apparent temperature or comfort index—is a temperature measure that takes into account the relative humidity. Based on human physiology and on clothing science, it measures how a given air temperature feels to the average person at a given relative humidity. The HI temperature is measured in the shade and assumes a wind speed of 5.6 mph (9 kph) and normal barometric pressure.

At low relative humidity, the HI is less than or equal to the air temperature. At higher relative humidity, the HI exceeds the air temperature. For example, according to the National Weather Service's (NWS) HI chart, if the air temperature is 70°F (21°C), the HI is 64°F (18°C) at 0% relative humidity and 72°F (22°C) at 100% relative humidity. At 95°F (35°C) and 55% relative humidity, the HI is 110°F (43°C). In very hot weather, humidity can raise the HI to extreme levels: at 115°F (46°C) and 40% relative humidity, the HI is 151°F (66°C). This is because humidity affects the body's ability to regulate internal heat through perspiration. The body feels warmer when it is humid because perspiration evaporates more slowly; thus the HI is higher.

The HI is used to predict the risk of physiological heat stress for an average individual. Caution is advised at an HI of 80–90°F (27–32°C): fatigue may result with prolonged exposure and physical activity. An HI of 90–105°F (32–41°C) calls for extreme caution, since sunstroke, muscle cramps, and heat exhaustion are possible. Danger warnings are issued at HIs of 105–130°F (41–54°C), when sunstroke and heat exhaustion are likely and there is a potential for heat stroke. Category IV, extreme danger, occurs at HIs above 130°F (54°C), when heatstroke and sunstroke are imminent.

Individual physiology influences how people are affected by high HIs. Children and older people are more vulnerable. Acclimatization (being used to the **climate**) can alleviate some of the danger. However sunburn can increase the effective HI by slowing the skin's ability to shed excess heat from blood vessels and through perspiration. Exposure to full sunlight can increase HI values by as much as 15°F (8°C). Winds, especially hot dry winds, also can increase the HI. In general, the NWS issues excessive heat alerts when the daytime HI reaches 105°F (41°C) and the nighttime HI stays above 80°F (27°C) for two consecutive days; however these values depend somewhat on the region or metropolitan area. In cities, high HIs often mean increased **air pollution**. The concentration of **ozone**, the major component of **smog**, tends to rise at ground level as the HI increases, causing respiratory problems for many people.

The National Center for Health **Statistics** estimates that heat exposure results in an average of 371 deaths annually in the United States. About 1,700 Americans died in the heat waves of 1980. In Chicago in 1995, more than 700 people died during a five-day heat wave when the nighttime HI stayed above 89°F (32°C).

At higher temperatures, the air can hold more water vapor; thus humidity and HI values increase as the **atmosphere** warms. Since the late nineteenth century, the mean annual surface temperature of the earth has risen between 0.5 and 1.0°F (0.3 and 0.6°C). According to the National Aeronautics and Space Administration, the five-year-mean temperature increased about 0.9°F (0.5°C) between 1975 and 1999, the fastest rate of recorded increase. In 1998 global surface temperatures were the warmest since the advent of reliable measurements and the 1990s accounted for seven of the 10 warmest years on record. Nighttime temperatures have been increasing twice as fast as daytime temperatures.

Greenhouse gases, including **carbon dioxide**, **methane**, **nitrous oxide**, and **chlorofluorocarbons**, increase the heat-trapping capabilities of the atmosphere. Evaporation from the ocean surfaces increased during the twentieth century, resulting in higher humidity that enhanced the **greenhouse effect**. It is projected that during the twenty-first century greenhouse gas concentrations will double or even quadruple from pre-industrial levels. Increased urbanization also contributes to global warming, as

buildings and roads hold in the heat. Climate simulations predict an average surface air temperature increase of 4.5–7°F (2.5–4°C) by 2100. This will increase the number of extremely hot days and, in temperate climates, double the number of very hot days, for an average increase in summer temperatures of 4–5°F (2–3°C). More heat-related illnesses and deaths will result.

The **National Oceanic and Atmospheric Administration** projects that the HI could rise substantially in humid regions of the tropics and sub-tropics. Warm, humid regions of the southeastern United States are expected to experience substantial increases in the summer HI due to increased humidity, even though temperature increases may be smaller than in the continental interior. Predictions for the increase in the summer HI for the Southeast United States over the next century range from 8–20°F (4–11°C).

Heavy metals and heavy metal poisoning

Heavy metals are generally defined as environmentally stable elements of high specific gravity and atomic weight. They have such characteristics as luster, ductility, malleability, and high electric and thermal conductivity. Whether based on their physical or chemical properties, the distinction between heavy metals and non-metals is not sharp. For example, **arsenic**, germanium, selenium, tellurium, and antimony possess chemical properties of both metals and non-metals. Defined as metalloids, they are often loosely classified as heavy metals. The category "heavy metal" is, therefore, somewhat arbitrary and highly non-specific because it can refer to approximately 80 of the 103 elements in the periodic table. The term "trace element" is commonly used to describe substances which cannot be precisely defined but most frequently occur in the **environment** in concentrations of a few **parts per million** (ppm) or less. Only a relatively small number of heavy metals such as **cadmium**, **copper**, iron, cobalt, zinc, **mercury**, vanadium, **lead**, **nickel**, chromium, manganese, molybdenum, silver, and tin as well as the metalloids arsenic and selenium are associated with environmental, plant, animal, or human health problems.

While the chemical forms of heavy metals can be changed, they are not subject to chemical/biological destruction. Therefore, after release into the environment they are persistent contaminants. Natural processes such as bedrock and **soil weathering**, wind and water **erosion**, volcanic activity, sea salt spray, and forest fires release heavy metals into the environment. While the origins of **anthropogenic** releases of heavy metals are lost in antiquity, they probably began as our prehistoric ancestors learned to recover metals such as gold, silver, copper, and tin from their ores and to produce bronze. The modern age of heavy metal **pollution** has its beginning with the Industrial Revolution. The rapid development of industry, intensive agriculture, **transportation**, and urbanization over the past 150 years, however, has been the precursor of today's environmental contamination problems. Anthropogenic utilization has also increased heavy metal distribution by removing the substances from localized ore deposits and transporting them to other parts of the environment. Heavy metal by-products result from many activities including: ore extraction and smelting, fossil fuel **combustion**, dumping and landfilling of industrial wastes, exhausts from leaded gasolines, steel, iron, cement and **fertilizer** production, refuse and wood combustion. Heavy metal cycling has also increased through activities such as farming, **deforestation**, construction, **dredging** of harbors, and the disposal of municipal sludges and industrial wastes on land.

Thus, anthropogenic processes, especially combustion, have substantially supplemented the natural atmospheric

emissions of selected heavy metals/metalloids such as selenium, mercury, arsenic, and antimony. They can be transported as gases or adsorbed on particles. Other metals such as cadmium, lead, and zinc are transported atmospherically only as particles. In either state heavy metals may travel long distances before being deposited on land or water.

The heavy metal contamination of soils is a far more serious problem than either air or **water pollution** because heavy metals are usually tightly bound by the organic components in the surface layers of the soil and may, depending on conditions, persist for centuries or millennia. Consequently, the soil is an important geochemical sink which accumulates heavy metals rapidly and usually depletes them very slowly by **leaching** into **groundwater** aquifers or bioaccumulating into plants. However, heavy metals can also be very rapidly translocated through the environment by erosion of the soil particles to which they are adsorbed or bound and redeposited elsewhere on the land or washed into rivers, lakes or oceans to the **sediment**.

The cycling, bioavailability, toxicity, transport, and fate of heavy metals are markedly influenced by their physico-chemical forms in water, sediments, and soils. Whenever a heavy metal containing **ion** or compound is introduced into an aquatic environment, it is subjected to a wide variety of physical, chemical, and biological processes. These include: hydrolysis, chelation, complexation, redox, biomethylation, precipitation and **adsorption** reactions. Often heavy metals experience a change in the chemical form or speciation as a result of these processes and so their distribution, bioavailability, and other interactions in the environment are also affected.

The interactions of heavy metals in aquatic systems are complicated because of the possible changes due to many dissolved and **particulate** components and non-equilibrium conditions. For example, the speciation of heavy metals is controlled not only by their chemical properties but also by environmental variables such as: 1) **pH**; 2) redox potential; 3) **dissolved oxygen**; 4) ionic strength; 5) temperature; 6) **salinity**; 7) alkalinity; 8) hardness; 9) concentration and **nature** of inorganic ligands such as carbonate, bicarbonate, sulfate, sulfides, chlorides; 10) concentration and nature of dissolved organic chelating agents such as organic acids, humic materials, **peptides**, and polyamino-carboxylates; 11) the concentration and nature of particulate matter with surface sites available for heavy metal binding; and 12) biological activity.

In addition, various **species** of bacteria can oxidize arsenate or reduce arsenate to arsenite, or oxidize ferrous iron to ferric iron, or convert mercuric ion to elemental mercury or the reverse. Various **enzyme** systems in living organisms can biomethylate a number of heavy metals. While it had been known for at least 60 years that arsenic and selenium could be biomethylated, **microorganisms** capable of converting inorganic mercury into monomethyl and dimethylmercury in lake sediments were not discovered until 1967. Since then, numerous heavy metals such as lead, tin, cobalt, antimony, platinum, gold, tellurium, thallium, and palladium have been shown to be biomethylated by bacteria and **fungi** in the environment.

As environmental factors change the chemical reactivities and speciation of heavy metals, they influence not only the mobilization, transport, and bioavailability, but also the toxicity of heavy metal ions toward biota in both freshwater and marine ecosystems. The factors affecting the toxicity and **bioaccumulation** of heavy metals by aquatic organisms include: 1) the chemical characteristics of the ion; 2) solution conditions which affect the chemical form (speciation) of the ion; 3) the nature of the response such as acute toxicity, bioaccumulation, various types of **chronic effects**, etc.; 4) the nature and condition of the aquatic animal such as age or life stage, species, or **trophic level** in the food chain. The extent to which most of the methylated metals are bioaccumulated and/or biomagnified is limited by the chemical and biological conditions and how readily the methylated metal is metabolized by an organism. At present, only methylmercury seems to be sufficiently stable to bioaccumulate to levels that can cause adverse effects in aquatic organisms. All other methylated metal ions are produced in very small concentrations and are degraded naturally faster than they are bioaccumulated. Therefore, they do not biomagnify in the food chain.

The largest proportion of heavy metals in water is associated with suspended particles, which are ultimately deposited in the bottom sediments where concentrations are orders of magnitude higher than those in the overlying or interstitial waters. The heavy metals associated with suspended particulates or bottom sediments are complex mixtures of: 1) weathering and erosion residues such as iron and **aluminum** oxyhydroxides, clays and other aluminosilicates; 2) methylated and non-methylated forms in organic matter such as living organisms, bacteria and algae, **detritus** and **humus**; 3) inorganic hydrous oxides and hydroxides, **phosphates** and silicates; and 4) diagenetically produced iron and manganese oxyhydroxides in the upper layer of sediments and sulfides in the deeper, anoxic layers.

In anoxic waters the precipitation of sulfides may control the heavy metal concentrations in sediments while in oxic waters adsorption, **absorption**, surface precipitation and **coprecipitation** are usually the mechanisms by which heavy metals are removed from the water column. Moreover, physical, chemical and microbiological processes in the sediments often increase the concentrations of heavy metals in the pore waters which are released to overlying waters by diffusion or as the result of consolidation and bioturbation.

Transport by living organisms does not represent a significant mechanism for local movement of heavy metals. However, accumulation by aquatic plants and animals can lead to important biological responses. Even low environmental levels of some heavy metals may produce subtle and chronic effects in animal populations.

Despite these adverse effects, at very low levels, some metals have essential physiological roles as micronutrients. Heavy metals such as chromium, manganese, iron, cobalt, molybdenum, nickel, vanadium, copper, and selenium are required in small amounts to perform important biochemical functions in plant and animal systems. In higher concentrations they can be toxic, but usually some biological regulatory mechanism is available by means of which animals can speed up their excretion or retard their uptake of excessive quantities.

In contrast, non-essential heavy metals are primarily of concern in terrestrial and aquatic systems because they are toxic and persist in living systems. Metal ions commonly bond with sulfhydryl and carboxylic **acid** groups in amino acids, which are components of proteins (enzymes) or polypeptides. This increases their bioaccumulation and inhibits excretion. For example, heavy metals such as lead, cadmium, and mercury bind strongly with -SH and $-SCH_3$ groups in cysteine and methionine and so inhibit the **metabolism** of the bound enzymes. In addition, other heavy metals may replace an essential element, decreasing its availability and causing symptoms of deficiency.

Uptake, translocation, and accumulation of potentially toxic heavy metals in plants differ widely depending on soil type, pH, redox potential, moisture, and organic content. Public health officials closely regulate the quantities and effects of heavy metals that move through the agricultural food chain to be consumed by human beings. While heavy metals such as zinc, copper, nickel, lead, arsenic, and cadmium are translocated from the soil to plants and then into the animal food chain, the concentrations in plants are usually very low and generally not considered to be an environmental problem. However, plants grown on soils either naturally enriched or highly contaminated with some heavy metals can bioaccumulate levels high enough to cause toxic effects in the animals or human beings that consume them.

Contamination of soils due to land disposal of sewage and industrial effluents and sludges may pose the most significant long term problem. While cadmium and lead are the greatest hazard, other elements such as copper, molybdenum, nickel, and zinc can also accumulate in plants grown on sludge-treated land. High concentrations can, under certain conditions, cause adverse effects in animals and human beings that consume the plants. For example, when soil contains high concentrations of molybdenum and selenium, they can be translocated into edible plant tissue in sufficient quantities to produce toxic effects in ruminant animals. Consequently, the U. S. **Environmental Protection Agency** has issued regulations which prohibit and/or tightly regulate the disposal of contaminated municipal and industrial sludges on land to prevent heavy metals, especially cadmium, from entering the food supply in toxic amounts. However, presently, the most serious known human toxicity is not through bioaccumulation from crops but from mercury in fish, lead in **gasoline**, paints and water pipes, and other metals derived from occupational or accidental exposure. *See also* Aquatic chemistry; Ashio, Japan; Atmospheric pollutants; Biomagnification; Biological methylation; Contaminated soil; Ducktown, Tennessee; Hazardous material; Heavy metals precipitation; Itai-Itai disease; Methylmercury seed dressings; Minamata disease; Smelters; Sudbury, Ontario; Xenobiotic

Heavy metals precipitation

The principle technology to remove metals pollutants from **wastewater** is by chemical precipitation. Chemical precipitation includes two secondary removal mechanisms, **coprecipitation** and **adsorption**. Precipitation processes are characterized by the solubility of the metal to be removed. They are generally designed to precipitate trace metals to their solubility limits and obtain additional removal by coprecipitation and adsorption during the precipitation reaction.

There are many different treatment variables that affect these processes. They include the optimum **pH**, the type of chemical treatments used, and the number of treatment stages, as well as the temperature and volume of wastewater, and the chemical specifications of the pollutants to be removed. Each of these variables directly influences treatment objectives and costs. Treatability studies must be performed to optimize the relevant variables, so that goals are met and costs minimized.

In theory, the precipitation process has two steps, nucleation followed by particle growth. Nucleation is represented by the appearance of very small particle seeds which are generally composed of 10–100 molecules. Particle growth

involves the addition of more atoms or molecules into this particle structure. The rate and extent of this process is dependent upon the temperature and chemical characteristics of the wastewater, such as the concentration of metal initially present and other ionic **species** present, which can compete with or form soluble complexes with the target metal species.

Heavy metals are present in many industrial wastewaters. Examples of such metals are **cadmium**, **copper**, **lead**, **mercury**, **nickel**, and zinc. In general, these metals can be complexed to insoluble species by adding sulfide, hydroxide, and carbonate ions to a solution. For example, the precipitation of copper (Cu) hydroxide is accomplished by adjusting the pH of the water to above 8, using precipitant **chemicals** such as lime ($Ca(OH)_2$) or sodium hydroxide (N_aOH). Precipitation of metallic carbonate and sulfide species can be accomplished by the addition of calcium carbonate or sodium sulfide. The removal of coprecipitive metals during precipitation of the soluble metals is aided by the presence of solid ferric oxide, which acts as an adsorbent during the precipitation reaction. For example, hydroxide precipitation of ferric chloride can be used as the source of ferric oxide for coprecipitation and adsorption reactions. Precipitation, coprecipitation, and adsorption reactions generate suspended solids which must be separated from the wastewater. Flocculation and clarification are again employed to assist in solids separation. The treatment is an important variable which must be optimized to effect the maximum metal removal possible.

Determining the optimal pH range to facilitate the maximum precipitation of metal is a difficult task. It is typically accomplished by laboratory studies, such as by-jar tests rather than theoretical calculations. Often the actual wastestream behaves differently, and the theoretical metal solubilities and corresponding optimal pH ranges can vary considerably from theoretical values. *See also* Heavy metals and heavy metal poisoning; Industrial waste treatment; Itai-itai disease; Minamata disease; Sludge; Waste management

Robert Louis Heilbroner (1919 –)

American economist and author

An economist by profession, Robert Heilbroner is the author of a number of books and articles that put economic theories and developments into historical perspective and relate them to contemporary social and political problems. He is especially noteworthy for his gloomy speculations on the future of a world confronted by the environmental limits to economic growth.

Born in New York City in 1919, Heilbroner received a bachelor's degree from Harvard University in 1940 and a Bronze Star for his service in World War II. In 1963 he earned a Ph.D. in economics from the New School for Social Research in New York, and in 1972, became the Norman Thomas Professor of Economics there. His books include *The Worldly Philosophers* (1955), *The Making of Economic Society* (1962), *Marxism: For and Against* (1980), and *The Nature and Logic of Capitalism* (1985). He has also served on the editorial board of the socialist journal *Dissent*.

In 1974, Heilbroner published *An Inquiry into the Human Prospect*, in which he argues that three "external challenges" confront humanity: the population explosion, the threat of war, and "the danger...of encroaching on the **environment** beyond its ability to support the demands made on it." Each of these problems, he maintains, arises from the development of scientific technology, which has increased human life span, multiplied weapons of destruction, and encouraged industrial production that consumes **natural resources** and pollutes the environment. Heilbroner believes that these challenges confront all economies, and that meeting them will require more than adjustments in economic systems. Societies will have to muster the will to make sacrifices.

Heilbroner goes on to argue that persuading people to make these sacrifices may not be possible. Those living in one part of the world are not likely to give up what they have for the sake of those in another part, and people living now are not likely to make sacrifices for **future generations**. His reluctant conclusion is that coercion is likely to take the place of persuasion. Authoritarian governments may well supplant democracies because "the passage through the gantlet ahead may be possible only under governments capable of rallying obedience far more effectively than would be possible in a democratic setting. If the issue for mankind is survival, such governments may be unavoidable, even necessary."

Heilbroner wrote *An Inquiry into the Human Prospect* in 1972 and 1973, but his position had not changed by the end of the decade. In a revised edition written in 1979, he continued to insist upon the environmental limits to economic growth: "the industrialized capitalist and socialist worlds can probably continue along their present growth paths" for about 25 years, at which point "we must expect...a general recognition that the possibilities for expansion are limited, and that social and economic life must be maintained within fixed...material boundaries." Heilbroner has published a number of books, including *21st Century Capitalism*

Robert L. Heilbroner. (Photograph by Jose Pelaez. W. W. Norton. Reproduced by permission.)

and *Visions of the Future*. He also received the New York Council for the Humanities Scholar of the Year award in 1994. Heilbroner currerently holds the position of Norman Thomas Professor of Economics, Emeritus, at the New School for Social Research, in New York City.

Hells Canyon

Hells Canyon is a stretch of canyon on the Snake River between Idaho and Oregon. This canyon, deeper than the Grand Canyon and formed in ancient basalt flows, contains some of the United States' wildest rapids and has provided extensive recreational and scenic boating since the 1920s. The narrow canyon has also provided outstanding dam sites. Hells Canyon became the subject of nationwide controversy between 1967 and 1975, when environmentalists challenged hydroelectric developers over the last stretch of free-flowing water in the Snake River from the border of Wyoming to the Pacific.

Historically Hells Canyon, over 100 mi (161 km) long, filled with rapids, and averaging 6,500 ft (1,983 m) deep, presented a major obstacle to travelers and explorers crossing the mountains and deserts of southern Idaho and eastern Oregon. Nez Percé, Paiute, Cayuse, and other Native American groups of the region had long used the area as a mild wintering ground with good grazing land for their horses. European settlers came for the modest timber and with cattle and sheep to graze. As early as the 1920s travelers were arriving in this scenic area for recreational purposes, with the first river runners navigating the canyon's rapids in 1928. By the end of the Depression the **Federal Power Commission** was urging regional utility companies to tap the river's hydroelectric potential, and in 1958 the first dam was built in the canyon.

Falling from the mountains in southern **Yellowstone National Park** through Idaho, and into the Columbia River, the Snake River drops over 7,000 vertical ft (2,135 m) in 1,000 mi (1,609 km) of river. This drop and the narrow gorges the river has carved presented excellent dam opportunities, and by the end of the 1960s there were 18 major **dams** along the river's course. By that time the river was also attracting great numbers of whitewater rafters and kayakers, as well as hikers and campers in the adjacent national forests. When a proposal was developed to dam the last free-running section of the canyon, protesters brought a suit to the United States Supreme Court. In 1967, Justice William O. Douglas led the majority in a decision directing the utilities to consider alternatives to the proposed dam.

Hells Canyon became a national environmental issue. Several members of Congress flew to Oregon to raft the river. The **Sierra Club** and other groups lobbied vigorously. Finally, in 1975 President Gerald Ford signed a bill declaring the remaining stretch of the canyon a National Scenic Waterway, creating a 650,000-acre (260,000-ha) Hells Canyon National **Recreation** Area, and adding 193,000 acres (77,200 ha) of the area to the National **Wilderness** Preservation System. *See also* Wild and Scenic Rivers Act; Wild river

Hazel Henderson (1933 –)

English/American environmental activist and writer

Hazel Henderson is an environmental activist and futurist who has called for an end to current "unsustainable industrial modes" and urges redress for the "unequal access to resources which is now so dangerous, both ecologically and socially."

Born in Clevedon, England, Henderson immigrated to the United States after finishing high school; she became a naturalized citizen in 1962. After working for several years as a free-lance journalist, she married Carter F. Henderson, former London bureau chief of the *Wall Street Journal* in 1957. Her activism began when she became concerned about **air quality** in New York City, where she was living. To raise public awareness, she convinced the FCC and television networks to broadcast the **air pollution index** with the weather report. She persuaded an advertising agency to donate their services to her cause and teamed up with a New York City councilman to co-found Citizens for Clean Air. Her endeavors were rewarded in 1967, when she was commended as Citizen of the Year by the New York Medical Society.

Henderson's career as an advocate for social and environmental reform took flight from there. She argued passionately against the spread of industrialism, which she called "pathological" and decried the use of an economic yardstick to measure quality of life. Indeed, she termed economics "merely politics in disguise" and even "a form of brain damage." Henderson believed that society should be measured by less tangible means, such as political participation, literacy, education, and health. "Per-capita income," she felt, is "a very weak indicator of human well-being."

She became convinced that traditional industrial development wrought little but "ecological devastation, social unrest, and downright hunger...I think of development, instead,...as investing in ecosystems, their restoration and management."

Even the fundamental idea of labor should, Henderson argued, "be replaced by the concept of 'Good Work'—which challenges individuals to grow and develop their faculties; to overcome their ego-centeredness by joining with others in common tasks; to bring forth those goods and services needed for a becoming existence; and to do all this with an ethical concern for the interdependence of all life forms..."

To advance her theories, Henderson has published several books, *Creative Alternative Futures: The End of Economics* (1978), *The Politics of the Solar Age: Alternatives to Economics* (1981), *Building a Win-Win World* (1996), *Toward Sustainable Communities: Resources for Citizens and Their Governments* (1998), and *Beyond Globalization: Shaping a Sustainable Global Economy* (1999). She has also contributed to several periodicals, and lectured at colleges and universities. In 1972 she co-founded the Princeton Center for Alternative Futures, of which she is still a director. She is a member of the board of directors for **Worldwatch Institute** and the Council for Economic Priorities, among other organizations. In 1982 she was appointed a Horace Allbright Professor at the University of California at Berkeley. In 1996, Henderson was awarded the Global Citizen Award.

Herbicide

Herbicides are chemical pesticides that are used to manage vegetation. Usually, herbicides are used to reduce the abundance of weedy plants, so as to release desired crop plants from **competition**. This is the context of most herbicide use in agriculture, forestry, and for lawn management. Sometimes herbicides are not used to protect crops, but to reduce the quantity or height of vegetation, for example along highways and transmission corridors. The reliance on herbicides to achieve these ends has increased greatly in recent decades, and the practice of chemical weed control appears to have become an entrenched component of the modern technological culture of humans, especially in agroecosystems.

The total use of pesticides in the United States in the mid-1980s was 957 million lb per year (434 million kg/year), used over 592,000 mi^2 (1.5 million km^2). Herbicides were most widely used, accounting for 68% of the total quantity [646 million lb per year [293 million kg/year]), and applied to 82% of the treated land [484,000 square miles

per year (121 million hectares/year)]. Note that especially in agriculture, the same land area can be treated numerous times each year with various pesticides.

A wide range of **chemicals** is used as herbicides, including:

- chlorophenoxy acids, especially **2,4-D** and **2,4,5-T**, which have an auxin-like growth-regulating property and are selective against broadleaved angiosperm plants;
- triazines such as **atrazine**, simazine, and hexazinone;
- chloroaliphatics such as dalapon and trichloroacetate;
- the phosphonoalkyl chemical, glyphosate, and
- inorganics such as various arsenicals, cyanates, and chlorates.

A "weed" is usually considered to be any plant that interferes with the productivity of a desired crop plant or some other human purpose, even though in other contexts weed **species** may have positive ecological and economic values. Weeds exert this effect by competing with the crop for light, water, and nutrients. Studies in Illinois demonstrated an average reduction of yield of corn or maize (*Zea mays*) of 81% in unweeded plots, while a 51% reduction was reported in Minnesota. Weeds also reduce the yield of small grains, such as wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*), by 25–50%.

Because there are several herbicides that are toxic to dicotyledonous weeds but not grasses, herbicides are used most intensively used in grain crops of the Gramineae. For example, in North America almost all of the area of maize cultivation is treated with herbicides. In part this is due to the widespread use of no-tillage cultivation, a system that reduces **erosion** and saves fuel. Since an important purpose of plowing is to reduce the abundance of weeds, the no-tillage system would be impracticable if not accompanied by herbicide use. The most important herbicides used in maize cultivation are atrazine, propachlor, alachlor, 2,4-D, and butylate. Most of the area planted to other agricultural grasses such as wheat, rice (*Oryza sativa*), and barley is also treated with herbicide, mostly with the phenoxy herbicides 2,4-D or MCPA.

The intended ecological effect of any **pesticide** application is to control a **pest** species, usually by reducing its abundance to below some economically acceptable threshold. In a few situations, this objective can be attained without important nontarget damage. For example, a judicious spot-application of a herbicide can allow a selective kill of large lawn weeds in a way that minimizes exposure to nontarget plants and animals.

Of course, most situations where herbicides are used are more complex and less well-controlled than this. Whenever a herbicide is broadcast-sprayed over a field or forest, a wide variety of on-site, nontarget organisms is affected, and sprayed herbicide also drifts from the target area. These cause ecotoxicological effects directly, through toxicity to nontarget organisms and ecosystems, and indirectly, by changing **habitat** or the abundance of food species of **wildlife**. These effects can be illustrated by the use of herbicides in forestry, with glyphosate used as an example.

The most frequent use of herbicides in forestry is for the release of small coniferous plants from the effects of competition with economically undesirable weeds. Usually the silvicultural use of herbicides occurs within the context of an intensive harvesting-and-management system, which may include **clear-cutting**, scarification, planting seedlings of a single desired species, spacing, and other practices.

Glyphosate is a commonly used herbicide in forestry and agriculture. The typical spray rate in silviculture is about 2.2–4.9 mi (1–2.2 kg) active ingredient/ha, and the typical projection is for one to two treatments per forest rotation of 40–100 years.

Immediately after an aerial application in forestry, glyphosate residues are about six times higher than litter on the forest floor, which is physically shielded from spray by overtopping foliage. The persistence of glyphosate residues is relatively short, with typical half-lives of two to four weeks in foliage and the forest floor, and up to eight weeks in **soil**. The disappearance of residues from foliage is mostly due to translocation and wash-off, but in the forest floor and soil glyphosate is immobile (and unavailable for root uptake or **leaching**) because of binding to organic matter and clay, and residue disappearance is due to microbial oxidation. Residues in oversprayed waterbodies tend to be small and short-lived. For example, two hours after a deliberate overspray on Vancouver Island, Canada, residues of glyphosate in stream water rose to high levels, then rapidly dissipated through flushing to only trace amounts 94 hours later.

Because glyphosate is soluble in water, there is no propensity for **bioaccumulation** in organisms in preference to the inorganic **environment**, or to occur in larger concentrations at higher levels of the **food chain/web**. This is in marked contrast to some other pesticides such as DDT, which is soluble in organic solvents but not in water, so it has a strong tendency to bioaccumulate into the fatty tissues of organisms.

As a plant poison, glyphosate acts by inhibiting the pathway by which four essential amino acids are synthesized. Only plants and some **microorganisms** have this metabolic pathway; animals obtain these amino acids from food. Consequently, glyphosate has a relatively small acute toxicity to animals, and there are large margins of toxicological safety in comparison with environmental exposures that are realistically expected during operational silvicultural sprays.

Acute toxicity of chemicals to mammals is often indexed by the oral dose required to kill 50% of a test popula-

tion, usually of rats (i.e., rat LD_{50}). The LD_{50} value for pure glyphosate is 5,600 mg/kg, and its silvicultural formulation has a value of 5,400 mg/kg. Compare these to LD_{50}s for some chemicals which many humans ingest voluntarily: nicotine 50 mg/kg, caffeine 366, acetylsalicylic **acid** (ASA) 1,700, sodium chloride 3,750, and **ethanol** 13,000. The documented risks of longer-term, chronic exposures of mammals to glyphosate are also small, especially considering the doses that might be received during an operational treatment in forestry.

Considering the relatively small acute and chronic toxicities of glyphosate to animals, it is unlikely that wildlife inhabiting sprayed clearcuts would be directly affected by a silvicultural application. However, glyphosate causes large habitat changes through species-specific effects on plant productivity, and by changing habitat structure. Therefore, wildlife such as birds and mammals could be secondarily affected through changes in vegetation and the abundance of their arthropod foods. These indirect effects of herbicide spraying are within the context of **ecotoxicology**. Indirect effects can affect the abundance and reproductive success of terrestrial and aquatic wild life on a sprayed site, irrespective of a lack of direct, toxic effects.

Studies of the effects of habitat changes caused by glyphosate spraying have found relatively small effects on the abundance and species composition of wildlife. Much larger effects on wildlife are associated with other forestry practices, such as clear-cutting and the broadcast spraying of insecticides. For example, in a study of clearcuts sprayed with glyphosate in Nova Scotia, Canada, only small changes in avian abundance and species composition could be attributed to the herbicide treatment. However, such studies of bird abundance are conducted by enumerating territories, and the results cannot be interpreted in terms of reproductive success. Regrettably, there are not yet any studies of the reproductive success of birds breeding on clearcuts recently treated with a herbicide. This is an important deficiency in terms of understanding the ecological effects of herbicide spraying in forestry.

An important controversy related to herbicides focused on the military use of herbicides during the Viet Nam war. During this conflict, the United States Air Force broadcast-sprayed herbicides to deprive their enemy of food production and forest cover. More than 5,600 mi^2 (14,503 km^2) were sprayed at least once, about 1/7 the area of South Viet Nam. More than 55 million lb (25 million kg) of 2,4-D, 43 million lb (21 million kg) of 2,4,5-T, and 3.3 million lb (1.5 million kg) of picloram were used in this military program. The most frequently used herbicide was a 50:50 formulation of 2,4,5-T and 2,4-D known as **Agent Orange**. The rate of application was relatively large, averaging about 10 times the application rate for silvicultural purposes. About 86% of spray missions were targeted against forests, and the remainder against cropland.

As was the military intention, these spray missions caused great ecological damage. Opponents of the practice labelled it "ecocide," i.e., the intentional use of anti-environmental actions as a military tactic. The broader ecological effects included severe damage to mangrove and tropical forests, and a great loss of wildlife habitat.

In addition, the Agent Orange used in Viet Nam was contaminated by the **dioxin** isomer known as TCDD, an incidental by-product of the manufacturing process of 2,4,5-T. Using post-Vietnam manufacturing technology, the contamination by TCDD in 2,4,5-T solutions can be kept to a concentration well below the maximum of 0.1 **parts per million** (ppm) set by the United States **Environmental Protection Agency** (EPA). However, the 2,4,5-T used in Viet Nam was grossly contaminated with TCDD, with a concentration as large as 45 ppm occurring in Agent Orange, and an average of about 2.0 ppm. Perhaps 243–375 lb (110–170 kg) of TCDD was sprayed with herbicides onto Vietnam. TCDD is well known as being extremely toxic, and it can cause **birth defects** and miscarriage in laboratory mammals, although as is often the case, toxicity to humans is less well understood. There has been great controversy about the effects on soldiers and civilians exposed to TCDD in Vietnam, but epidemiological studies have been equivocal about the damages. It seems likely that the effects of TCDD added little to human **mortality** or to the direct ecological effects of the herbicides that were sprayed in Vietnam.

A preferable approach to pesticide use is **integrated pest management** (IPM). In the context of IPM, pest control is achieved by employing an array of complementary approaches, including:

- use of natural predators, **parasites**, and other biological controls;
- use of pest-resistant varieties of crops;
- environmental modifications to reduce optimality of pest habitat;
- careful monitoring of pest abundance; and
- a judicious use of pesticides, when necessary as a component of the IPM strategy.

A successful IPM program can greatly reduce, but not necessarily eliminate, the reliance on pesticides.

With specific relevance to herbicides, more research into organic systems and into procedures that are pest-specific are required for the development of IPM systems. Examples of pest-specific practices are the biological control of certain introduced weeds, for example:

- St. John's wort (*Hypericum perforatum*) is a serious weed of pastures of the United States Southwest because it is

toxic to cattle, but it was controlled by the introduction in 1943 of two herbivorous leaf beetles;

- the prickly pear cactus (*Opuntia* spp.) became a serious weed of Australian **rangelands** after it was introduced as an ornamental plant, but it has been controlled by release of the moth *Cactoblastis cactorum*, whose larvae feed on the cactus.

Unfortunately, effective IPM systems have not yet been developed for most weed problems for which herbicides are now used. Until there are alternative, pest-specific methods to achieve an economically acceptable degree of control of weeds in agriculture and forestry, herbicides will continue to be used for that purpose. *See also* Agricultural chemicals

Heritage Conservation and Recreation Service

The Heritage Conservation and **Recreation** Service (HCRS) was created in 1978 as an agency of the U. S. Department of the Interior (Secretarial Executive Order 3017) to administer the National Heritage Program initiative of President Carter. The new agency was an outgrowth of and successor to the former Bureau of Outdoor Recreation. The HCRS resulted from the consolidation of some 30 laws, executive orders and interagency agreements that provided federal funds to states, cities and local community organizations to acquire, maintain, and develop historic, natural and recreation sites. HCRS focused on the identification and protection of the nation's significant natural, cultural and recreational resources. It classified and established registers for heritage resources, formulated policies and programs for their preservation, and coordinated federal, state and local resource and recreation policies and actions. In February 1981 HCRS was abolished as an agency and its responsibilities were transferred to the **National Park Service**.

Hetch Hetchy Reservoir

The Hetch Hetchy Reservoir, located on the Tuolumne River in **Yosemite National Park**, was built to provide water and hydroelectric power to San Francisco. Its creation in the early 1900s led to one of the first conflicts between preservationists and those favoring utilitarian use of **natural resources**. The controversy spanned the presidencies of Roosevelt, Taft, and Wilson.

A prolonged conflict between San Francisco and its only water utility, Spring Valley Water Company, drove the city to search for an independent water supply. After surveying several possibilities, the city decided to build a dam and reservoir in the Hetch Hetchy Valley because the river there could supply the most abundant and purest water. This option was also the least expensive, since the city planned to use the dam to generate hydroelectric power. It would also provide an abundant supply of **irrigation** water for area farmers and the **recreation** potential of a new lake.

The city applied to the U. S. Department of the Interior in 1901 for permission to construct the dam, but the request was not approved until 1908. The department then turned the issue over to Congress to work out an exchange of land between the federal government and the city. Congressional debate spanned several years and produced a number of bills. Part of the controversy involved the Right of Way Act of 1901, which gave Congress power to grant rights of way through government lands; some claimed this was designed specifically for the Hetch Hetchy project.

Opponents of the project likened the valley to Yosemite on a smaller scale. They wanted to preserve its high cliff walls, waterfalls, and diverse plant **species**. One of the most well-known opponents, **John Muir**, described the Hetch Hetchy Valley as "a grand landscape garden, one of Nature's rarest and most precious mountain temples." Campers and mountain climbers fought to save the campgrounds and trails that would be flooded.

As the argument ensued, often played out in newspapers and other public forums, overwhelming national opinion appeared to favor the preservation of the valley. Despite this public support, a close vote in Congress led to the passage of the Raker Act, allowing the O'Shaughnessy Dam and Hetch Hetchy Reservoir to be constructed. President Woodrow Wilson signed the bill into law on December 19, 1913.

The Hetch Hetchy Reservoir was completed in 1923 and still supplies water and electric power to San Francisco. In 1987, Secretary of the Interior Donald Hodel created a

brief controversy when he suggested tearing down O'Shaughnessy Dam. *See also* Economic growth and the environment; Environmental law; Environmental policy

Heterotroph

A heterotroph is an organism that derives its nutritional **carbon** and energy by oxidizing (i.e., decomposing) organic materials. The higher animals, **fungi**, actinomycetes, and most bacteria are heterotrophs. These are the biological consumers that eventually decompose most of the organic matter on the earth. The **decomposition** products then are available for chemical or biological **recycling**. *See also* Biogeochemical cycles; Oxidation reduction reactions

High-grading (mining, forestry)

The practice of high-grading can be traced back to the early days of the California gold rush, when miners would sneak into claims belonging to others and steal the most valuable pieces of ore. The practice of high-grading remains essentially unchanged today. An individual or corporation will enter an area and selectively mine or harvest only the most valuable specimens, before moving on to a new area. High-grading is most prevalent in the mining and timber industries. It is not uncommon to walk into a forest, particularly an **old-growth forest**, and find the oldest and finest specimens marked for harvesting. *See also* Forest management; Strip mining

High-level radioactive waste

High-level **radioactive waste** consists primarily of the by-products of nuclear **power plants** and defense activities. Such wastes are highly radioactive and often decay very slowly. They may release dangerous levels of radiation for hundreds or thousands of years. Most high-level radioactive wastes have to be handled by remote control by workers who are protected by heavy shielding. They present, therefore, a serious health and environmental hazard. No entirely satisfactory method for disposing of high-level wastes has as yet been devised. Currently, the best approach seems to involve immobilizing the wastes in a glass-like material and then burying them deep underground. *See also* Low-level radioactive waste; Radioactive decay; Radioactive pollution; Radioactive waste management; Radioactivity

High-solids reactor

Solid waste disposal is a serious problem in the United States and other developed countries. Solid waste can constitute valuable raw materials for commercial and industrial operations, however, and one of the challenges facing scientists is to develop an economically efficient method for utilizing it.

Although the concept of bacterial waste conversion is simple, achieving an efficient method for putting the technique into practice is difficult. The main problem is that efficiency of conversion requires increasing the ratio of solids to water in the mixture, and this makes mixing more difficult mechanically. The high-solids reactor was designed by scientists at the **Solar Energy** Research Institute (SERI) to solve this problem. It consists of a cylindrical tube on a horizontal axis, and an agitator shaft running through the middle of it, which contains a number of Teflon-coated paddles oriented at 90 degrees to each other. The pilot reactors operated by SERI had a capacity of 2.6 gal (10 l).

SERI scientists modeled the high solids reactor after similar devices used in the **plastics** industry to mix highly viscous materials. With the reactor, they have been able to process materials with 30–35% solids content, while existing reactors normally handle wastes with five to eight% solid content. With higher solid content, SERI reactors have achieved a yield of **methane** five to eight times greater than that obtained from conventional mixers. Researchers hope to be able to process wastes with solid content ranging anywhere from zero to 100%. They believe that they can eventually achieve 80% efficiency in converting **biomass** to methane.

The most obvious application of the high-solids reactor is the processing of municipal solid wastes. Initial tests were carried out with **sludge** obtained from **sewage treatment** plants in Denver, Los Angeles, and Chicago. In all cases, conversion of solids in the sludge to methane was successful, and other applications of the reactor are also being considered. For example, it can be used to leach out **uranium** from mine wastes: **anaerobic** bacteria in the reactor will reduce uranium in the wastes and the uranium will then be absorbed on the bacteria or on **ion exchange** resins. The use of the reactor to clean **contaminated soil** is also being considered in the hope is that this will provide a desirable alternative to current processes for cleaning **soil**,

which create large volumes of contaminated water. *See also* Biomass fuel; Solid waste incineration; Solid waste recycling and recovery; Solid waste volume reduction; Waste management

Hiroshima, Japan

Hiroshima is a beautiful modern city located near the southwestern tip of the main Japanese island of Honshu. It had been a military center with the headquarters of the Japanese southern army and a military depot prior to the end of World War II. The city is now a manufacturing center with a major university and medical school. It is most profoundly remembered because it was the first city to be exposed to the devastation of an atomic bomb.

At 8:15 A.M. on the morning of August 6, 1945, a single B29 bomber flying in from Tinian Island in the Marinas released the bomb at 2,000 ft (606.6 m) above the city. The target was a "T"-shaped bridge near the city center. The only surviving building in the city center after the atomic bomb blast was a domed cement building at ground zero, just a few yards from the bridge. An experimental bomb developed by the Manhattan Project had been exploded at Alamagardo, New Mexico, only a few weeks earlier. The Alamagardo bomb had the explosive force of 15,000 tons of TNT. The Hiroshima uranium-235 bomb, with the explosive power of 20,000 tons of TNT, was even more powerful than the New Mexico bomb. The immediate effect of the bomb was to destroy by blast, winds, and fire an area of 4.4 mi^2 (7 km^2). Two-thirds of the city was destroyed. A portion of Hiroshima was protected from the blast by hills, and this is all that remains of the old city. Destruction of human lives was caused immediately by the blast force of the bomb or by burns or **radiation sickness** later. Seventy-five thousand people were killed or were fatally wounded; there was an equal number of wounded survivors. Nagasaki, to the south and west of Hiroshima, was bombed on August 9, 1945, with much loss of life. The bombing of these two cities brought World War II to a close. The lessons that Hiroshima (and Nagasaki) teach are the horrors of war with its random killing of civilian men, women, and children. That is the major lesson—war is horrible with its destruction of innocent lives.

The why of Hiroshima should be taken in the context of the battle for Okinawa which occurred only weeks before. America forces suffered 12,000 dead with 36,000 wounded in the battle for that small island 350 mi (563.5 km) from the mainland of Japan. The Japanese were reported to have lost 100,000 men. The determination of the Japanese to defend their homeland was well known, and it was estimated that the invasion of Japan would cost no less than 500,000 American lives. Japanese casualties were expected to be larger. It was the military judgment of the American President that a swift termination of the war would save more lives than it would cost; both American and Japanese. Whether this rationale for the atomic bombing of Hiroshima was correct, i.e., whether more people would have died if Japan was invaded, will never be known. However, it certainly is a fact that the war came to a swift end after the bombing of the two cities.

The second lesson to be learned from Hiroshima is that **radiation exposure** is hazardous to human health and radiation damage results in radiation sickness and increased **cancer** risk. It had been known since the development of x rays at the turn of the century that radiation has the potential to cause cancer. However, the thousands of survivors at Hiroshima and Nagasaki were to become the largest group ever studied for radiation damage. The Atomic Bomb Casualty Commission, now referred to as the Radiation Effects Research Foundation (RERF), was established to monitor the health effects of radiation exposure and has studied these survivors since the end of World War II. The RERF has reported a 10–15 times excess of all types of **leukemia** among the survivors compared with populations not exposed to the bomb. The leukemia excess peaked four to seven years after exposure but still persists among the survivors. All forms of cancer tended to develop more frequently in heavily irradiated individuals, especially children under the age of 10 at the time of exposure. Thyroid cancer was also increased in these children survivors of the bomb.

War is destructive to human life. The particular kind of destruction at Hiroshima, due to an atomic bomb, continues to be relentlessly destructive. The city of Hiroshima is known as a Peace City.

[*Robert G. McKinnell*]

Holistic approach

First formulated by Jan Smuts, holism has been traditionally defined as a philosophical theory that states that the determining factors in **nature** are wholes which are irreducible to the sum of their parts and that the **evolution** of the universe is the record of the activity and making of such wholes. More generally, it is the concept that wholes cannot be analyzed into parts or reduced to discrete elements without unexplainable residuals. Holism may also be defined by what it is not: it is not synonymous with organicism; holism does not require an entity to be alive or even a part of living processes. And neither is holism confined to spiritual mysticism, unaccessible to scientific methods or study.

The holistic approach in **ecology** and **environmental science** derives from the idea proposed by Harrison Brown that "a precondition for solving [complex] problems is a realization that all of them are interlocked, with the result that they cannot be solved piecemeal." For some scholars holism is the rationale for the very existence of ecology. As David Gates notes, "the very definition of the discipline of ecology implies a holistic study."

The holistic approach has been successfully applied to environmental management. The United States **Forest Service**, for example, has implemented a multi-level approach to management that takes into account the complexity of forest ecosystems, rather than the traditional focus on isolated incidents or problems.

Some people believe that a holistic approach to nature and the world will counter the effects of "reductionism"—excessive individualism, atomization, mechanistic worldview, objectivism, materialism, and anthropocentrism. Advocates of holism claim that its emphasis on connectivity, community, processes, networks, participation, synthesis, systems, and emergent properties will undo the "ills" of reductionism. Others warn that a balance between reductionism and holism is necessary. American ecologist Eugene Odum mandated that "ecology must combine holism with reductionism if applications are to benefit society." Parts and wholes, at the macro- and micro-level, must be understood.

The basic lesson of a combined and complementary parts-whole approach is that every entity is both part *and* whole—an idea reenforced by Arthur Koestler's concept of a *holon*. A holon is any entity that is both a part of a larger system and itself a system made up of parts. It is essential to recognize that holism can include the study of *any* whole, the entirety of any individual in all its ramifications, without implying any organic analogy other than organisms themselves. A holistic approach alone, especially in its extreme form, is unrealistic, condemning scholars to an unproductive wallowing in an unmanageable complexity. Holism and reductionism are both needed for accessing and understanding an increasingly complex world. *See also* Environmental ethics

Homeostasis

Humans, all other organisms, and even ecological systems, live in an **environment** of constant change. The persistently shifting, modulating, and changing milieu would not permit survival, if it were not for the capacity of biological systems to respond to this constant flux by maintaining a relatively stable internal environment. An example taken from mammalian biology is temperature which appears to be "*fixed*" at approximately 98.6°F (37°C). While humans can be exposed to extreme summer heat, and arctic mammals survive intense cold, body temperature remains constant within vary narrow limits. Homeostasis is the sum total of all the biological responses that provide internal equilibrium and assure the maintenance of conditions for survival.

The human **species** has a greater variety of living conditions than any other organism. The ability of humans to live and reproduce in such diverse circumstances is due to a combination of homeostatic mechanisms coupled with cultural (behavioral) responses.

The scientific concept of homeostasis emerged from two scientists: Claude Bernard, a French physiologist, and Walter Bradford Cannon, an American physician. Bernard contrasted the external environment which surrounds an organism and the internal environment of that organism. He was, of course, aware that the external environment fluctuated considerably in contrast to the internal environment which remained remarkably constant. He is credited with the enunciation of the constancy of the internal environment ("*La fixité du milieu intérieur...*") in 1859. Bernard believed that the survival of an organism depended upon this constancy, and he observed it not only in temperature control but in the regulation of all of the systems that he studied. The concept of the stable "*milieu intérieur*" has been accepted and extended to the many organ systems of all higher vertebrates. This precise control of the internal environment is effected through hormones, the autonomic nervous system, endocrines, etc.

The term "homeostasis," derived from the Greek *homoios* meaning similar and *stasis* meaning to stand, suggests an internal environment which remains relatively similar or the same through time. The term was devised by Cannon in 1929 and used many times subsequently. Cannon noted that, in addition to temperature, there were complex controls involving many organ systems that maintained the internal **stability** within narrow limits. When those limited are exceeded, there is a reaction in the opposite direction that brings the condition back to normal, and the reactions returning the system to normal is referred to as negative feedback. Both Bernard and Cannon were concerned with human physiology. Nevertheless, the concept of homeostasis is applied to all levels of biological organization from the molecular level to ecological systems, including the entire **biosphere**. Engineers design self-controlling machines known as servomechanisms with feedback control by means of a sensing device, an amplifier which controls a servomotor which in turn runs the operation of the device. Examples of such devices are the thermostats which control furnace heat in a home or the more complicated automatic pilots of aircraft. While the human-made servomechanisms have similarities to biological homeostasis, they are not considered here.

As indicated above, temperature is closely regulated in humans and other homeotherms (birds and mammals). The human skin has thermal receptors sensitive to heat or cold. If cold is encountered, the receptors notify an area of the brain known as the hypothalamus via a nerve impulse. The hypothalamus has both a heat-promoting center and a heat-losing center, and, with cold, it is the former which is stimulated. Thyroid-releasing hormone, produced in the

hypothalamus, causes the anterior pituitary to release thyroid stimulating hormone which, in turn, causes the thyroid gland to increase production of thyroxine which results in increased **metabolism** and therefore heat. Sympathetic nerves from the hypothalamus stimulate the adrenal medulla to secrete epinephrine and norepinephrine into the blood which also increases body metabolism and heat. Increased muscle activity will generate heat and that activity can be either voluntary (stamping the feet for instance) or involuntary (shivering). Since heat is dissipated via body surface blood vessels, the nervous system causes surface vasoconstriction to decrease that heat loss. Further, the small quantity of blood that does reach the surface of the body, where it is chilled, is reheated by countercurrent heat exchange resulting from blood vessels containing cold blood from the limbs running adjacent to blood vessels from the body core which contain warm blood. The chilled blood is prewarmed prior to returning to the body core. A little noted response to chilling is the voluntary reaching for a jacket or coat to minimize heat loss.

The body responds with opposite results when excessive heat is encountered. The individual tends to shed unnecessary clothing, and activity is reduced to minimize metabolism. Vasodilation of superficial blood vessels allows for radiation of heat. Sweat is produced, which by evaporation reduces body heat. It is clear that the maintenance of body temperature is closely controlled by a complex of homeostasis mechanisms.

Each step in temperature regulation is controlled by negative feedback. As indicated above, with exposure to cold the hypothalamus, through a series of steps, induces the synthesis and release of thyroxine by the thyroid gland. What was not indicated above was the fact that elevated levels of thyroxine control the level of activity of the thyroid by negative feedback inhibition of thyroid stimulating hormone. An appropriate level of thyroid hormone is thus maintained. In contrast, with inadequate thyroxine, more thyroid stimulating hormone is produced. Negative feedback controls assure that any particular step in homeostasis does not deviate too much from the normal.

Historically, biologists have been particularly impressed with mammalian and human homeostasis. Lower vertebrates have received less attention. However, while internal physiology may vary more in a frog than in a human, there are mechanisms which assure the survival of **frogs**. For instance, when the ambient temperature drops significantly in the autumn in northern latitudes, leopard frogs move into lakes or rivers which do not freeze. Moving into lakes and rivers is a behavioral response to a change in the external environment which results in internal temperature stability. The metabolism and structure of the frog is inadequate to protect the frog from freezing, but the specific heat of the water is such that freezing does not occur except at the surface of the overwintering lake or river. Even though life at the bottom of a lake with an ice cover moves at a slower pace than during the warm summer months, a functioning circulatory system is essential for survival. In general, frog blood (not unlike crankcase oil prior to the era of multiviscosity oil) increases in viscosity with as temperature decreases. Frog blood, however, decreases in viscosity with the prolonged autumnal and winter cold temperatures, thus assuring adequate circulation during the long nights under an ice cover. This is another control mechanism that assures the survival of frogs by maintaining a relatively stable internal environment during the harsh winter. With a return of a warm external environment, northern leopard frogs leave cold water to warm up under the spring sun. Warm temperature causes frog blood viscosity to increase to summer levels. It may be that the behavioral and physiological changes do not prevent oscillations that would be unsuitable for warm blooded animals but, in the frog, the fluctuations do not interfere with survival, and in biology, that is all that is essential.

There is homeostasis in ecological systems. Populations of animals in complex systems fluctuate in numbers, but the variations in numbers are generally between limits. For example, predators survive in adequate numbers as long as prey are available. If predators become too great in number, the population of prey will diminish. With fewer prey, the numbers of predators plummet through negative feedback thus permitting recovery of the preyed upon species. The situation becomes much more complex when other food sources are available to the predator.

Many organisms encounter a negative feedback on growth rate with crowding. This density dependent population control has been studied in larval frogs, as well as many other organisms, where excretory products seem to specifically inhibit the crowded species but not other organisms in the same environment. Even with adequate food, high density culture of laboratory mice results in negative feedback on reproductive potential with abnormal gonad development and delayed sexual maturity. Density independent factors affecting populations are important in population control but would not be considered homeostasis. **Drought** is such a factor, and its effects can be contrasted with crowding. Populations of tadpoles will drop catastrophically when breeding ponds dry. Instead of fluctuating between limits (with controls), all individuals are affected the same (i.e., they die). The area must be repopulated with immigrants at a subsequent time, and the **migration** can be considered a population homeostatic control. The inward migration results in maintenance of population within the geographic area and aids in the survival of the species.

Homestead Act (1862)

The Homestead Act was signed into law in 1862. It was a legislative offer on a vast scale of free homesteads on unappropriated public lands. Any citizen (or alien who filed a declaration of intent to become a citizen), who had reached the age of 21, and was the head of a family could acquire title to a stretch of **public land** of up to 160 acres (65 ha) after living on it and farming it for five years. The only payment required was administrative fees. The settler could also obtain the land without the requirement of residence and cultivation for five years, against payment of $1.25 per acre. With the advent of machinery to mechanize farm labor, 160-acre (65 ha) tracts soon became uneconomical to operate, and Congress modified the original act to allow acquisition of larger tracts. The Homestead Act is still in effect, but good unappropriated land is scarce. Only Alaska still offers opportunities for homesteaders.

The Homestead Act was designed to speed development of the United States and to achieve an equitable distribution of wealth. Poor settlers, who lacked the capital to buy land, were now able to start their own farms. Indeed, the act contributed greatly to the growth and development of the country, particularly in the period between the Civil War and World War I, and it did much to speed settlement west of the Mississippi River. In all, well over a quarter of a billion acres of land has been distributed under the Homestead Act and its amendments. However, only a small percentage of land granted under the act between 1862 and 1900 was in fact acquired by homesteaders. According to estimates, only at most 1 of every 6 acres (0.4 of every 2.4 ha) and possibly only 1 in 9 acres (0.4 in 3.6 ha) passed into the hands of family farmers.

The railroad companies and land speculators obtained the bulk of the land, sometimes through gross fraud using dummy entrants. Moreover, the railroads often managed to get the best land while the homesteaders, ignorant of farming conditions on the Plains, often ended up with tracts least suitable to farming. Speculators frequently encouraged settlement on land that was too dry or had no sources of water for domestic use. When the homesteads failed, many settlers sold the land to speculators.

The environmental consequences of the Homestead Act were many and serious. The act facilitated railroad development, often in excess of **transportation** needs. In many instances, competing companies built lines to connect the same cities. Railroad development contributed significantly to the destruction of **bison** herds, which in turn led to the destruction of the way of life of the Plains Indians. Cultivation of the Plains caused wholesale destruction of the vast prairies, so that whole ecological systems virtually disappeared. Overfarming of semi-arid lands led to another environmental disaster, whose consequences were fully experienced only in the 1930s. The great **Dust Bowl**, with its terrifying dust storms, made huge areas of the country unlivable.

The Homestead Act was based on the notion that land held no value unless it was cultivated. It has now become clear that reckless cultivation can be self-destructive. In many cases, unfortunately, the damage can no longer be undone.

Horizon

Layers in the **soil** develop because of the additions, losses, translocations, and transformations that take place as the soil ages. The soil layers occur as a result of water percolating through the soil and **leaching** substances downward. The layers are parallel to the soil surface and are called horizons. Horizons will vary from the surface to the **subsoil** and from one soil to the next because of the different intensities of the above processes. Soils are classified into different groups based on the characteristics of the horizons.

Horseshoe crabs

The horseshoe crab (*Limulus polyphemus*) is the American **species** of a marine animal that is only a distant relation of crustaceans like crabs and lobsters. Horseshoe crabs are more closely related to spiders and scorpions. The crabs have been called "living fossils" because the genus dates back millions of years, and *Limulus* evolved very little over the years.

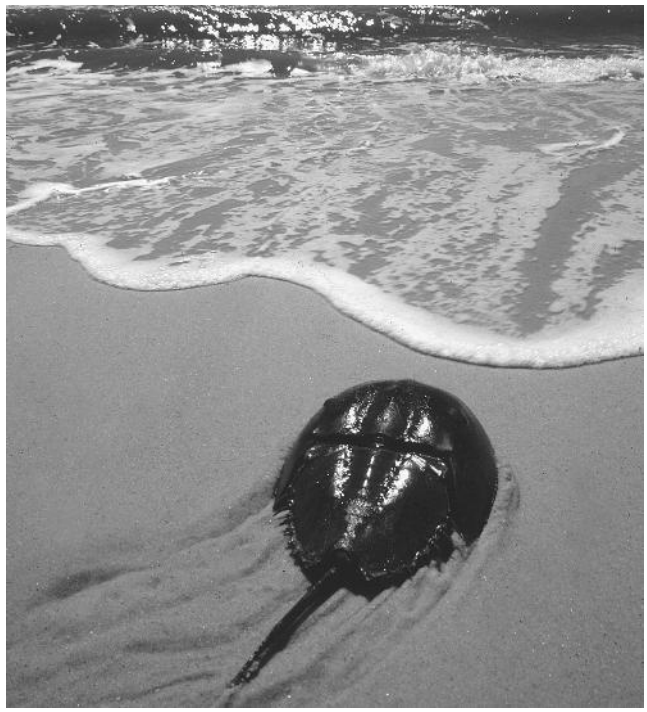
Fossils found in British Columbia indicate that the ancestors of horseshoe crabs were in North America about 520 million years ago. During the late twentieth century, the declining horseshoe crab population concerned environmentalists. Horseshoe crabs are a vital food source for dozens of species of birds that migrate from South America to the Arctic Circle. Furthermore, crabs are collected for medical

research. After blood is taken from the crabs, they are returned to the ocean.

American horseshoe crabs live along the Atlantic Ocean coastline. Crab **habitat** extends south from Maine to the Yucatán in the Gulf of Mexico. Several other crab species are found in Southeast Asia and Japan.

The American crab is named for its helmet-like shell that is shaped like a horseshoe. *Limulus* has a sharp tail shaped like a spike. The tail helps the crab move through the sand. If the crab tips over, the tail serves as a rudder so the crab can get back on its feet. The horseshoe crab is unique; its blood is blue and contains **copper**. The blood of other animals is red and contains iron.

Mature female crabs measure up to 24 inches in length. Males are about two-thirds smaller. Horseshoe crabs can live for 19 years, and they reach sexual maturity in 10 years. The crabs come to shore to spawn in late May and early June. They spawn the during the phases of the full and new moon. The female digs nests in the sand and deposits from 200 to 300 eggs in each pit. The male crab fertilizes the eggs with sperm, and the egg clutch is covered with sand.



During the spawning season, a female crab could deposit as many as 90,000 eggs. This spawning process coincides with the **migration** of shorebirds. Flocks of birds like the red knot and the sandpiper eat their fill of crab eggs before continuing their northbound migration.

Through the years, people found a variety of uses for horseshoe crabs. During the sixteenth century, Native Americans in South Carolina attached the tails to the spears that they used to catch fish. In the nineteenth century, people ground the crabs up for use as **fertilizer** or food for chickens and hogs.

During the twentieth century, researchers learned much about the human eye by studying the horseshoe crab's compound eye. Furthermore, researchers discovered that the crab's blood contained a special clotting agent that could be used to test the purity of new drugs and intravenous solutions. The agent called *Limulus Amoebocyte Lysate* is obtained by collecting horseshoe crabs during the spawning season. Crabs are bled and then returned to the beach.

Horseshoe crabs are also used as bait. The harvesting of crabs increased sharply during the 1990s when people in the fishing industry used crabs as bait to catch eels and conch. The annual numbers of crabs harvested jumped from the thousands to the millions during the 1990s, according to environmental groups and organizations like the **National Audubon Society**.

The declining horseshoe crab population could affect millions of migrating birds. The Audubon Society reported seeing fewer birds at the Atlantic beaches where horseshoe crabs spawn. In the spring of 2000, scientists said that birds appeared undernourished. Observers doubted that they would complete their journey to the Arctic Circle.

A horseshoe crab (*Limulus polyphemus*). (©John M. Burnley, National Audubon Society Collection. Photo Researchers Inc. Reproduced by permission.)

The Audubon Society and environmental groups have campaigned for state and federal regulations to protect horseshoe crabs. By 2002, coastal states and the Atlantic States Marine Fisheries Commission had set limits on the amount of crabs that could be harvested. The state of Virginia made bait bags mandatory when fishing with horseshoe crab bait. The mesh bag made of hard plastic holds the crab. That made it more difficult for predators to eat the crab so fewer *Limulus*crabs were needed as bait.

Furthermore, the federal government created a 1,500-square-mile refuge for horseshoe crabs in Delaware Bay. The refuge extends from Ocean City, New Jersey to north of Ocean City, Maryland. As of March of 2002, harvesting was banned in the refuge. People who took crabs from the area faced a fine of up to $100,000, according to the National Marine Fisheries Service.

As measures like those were enacted, marine biologists said that it could be several decades before the crab population increased. One reason for slow **population growth** was that it takes crabs 10 years to reach maturity.

Hospital wastes

see **Medical waste**

Household waste

Household waste is commonly referred to as **garbage** or trash. As the population of the world expands, so does the amount of waste produced. Generally, the more automated and industrialized human societies become, the more waste they produce. For example, the industrial revolution introduced new manufactured products and new manufacturing processes that added to household **solid waste** and industrial waste. Modern consumerism and the excess packaging of many products also contribute significantly to the increasing amount of solid waste.

Much of the trash Americans produce (about 40%) is paper and paper products. Paper accounts for more than 71 million tons of garbage. Yard wastes are the next most common waste, contributing more than 31 million tons of solid waste. Metals account for more than 8% of all household waste, and **plastics** are close behind with another 8% or 14 million tons. America's trash also contains about 7% glass and nearly 20 million tons of other materials like **rubber**, textiles, leather, wood, and inorganic wastes. Much of the waste comes from packaging materials. Other types of waste produced by consumers are durable goods such as tires, appliances, and furniture, while other household solid waste is made up of non-durable goods such as paper, disposable products, and clothing. Many of these items could be recycled and reused, so they also can be considered a non-utilized resource.

In less industrialized times and even today in many developing countries, households and industries disposed of unwanted materials in bodies of water or in land dumps. However, this practice creates undesirable effects such as health hazards and foul odors. Open dumps serve as breeding grounds for disease-carrying organisms such as rats and insects. As the **first world** became more alert to environmental hazards, methods for waste disposal were studied and improved. Today, however, governments, policymakers, and individuals still wrestle with the problem of how to improve methods of waste disposal, storage, and **recycling**.

In 1976, the United States Congress passed the **Resource Conservation and Recovery Act** (RCRA) in an effort to protect human health and the **environment** from hazards associated with waste disposal. In addition, the act aims to conserve energy and **natural resources** and to reduce the amount of waste Americans generate. Further, the RCRA promotes methods to manage waste in an environmentally sound manner. The act covers regulation of solid waste, **hazardous waste**, and underground storage tanks that hold **petroleum** products and certain **chemicals**.

Most household solid waste is removed from homes through community garbage collection and then taken to landfills. The garbage in landfills is buried, but it can still produce noxious odors. In addition, rainwater can seep through **landfill** sites and leach out pollutants from the landfill trash. These are then carried into nearby bodies of water. Pollutants can also contaminate **groundwater**, which in turn leads to contamination of drinking water.

In order to fight this problem, sanitary landfills were developed. Clay or plastic liners are placed in the ground before garbage is buried. This helps prevent water from seeping out of the landfill and into the surrounding environment. In sanitary landfills, each time a certain amount of waste is added to the landfill, it is covered by a layer of **soil**. At a predetermined height the site is capped and covered with dirt. Grass and trees can be planted on top of the capped landfill to help prevent **erosion** and to improve the look of the site. Sanitary landfills are more expensive than open pit dumps, and many communities do not want the stigma of having a landfill near them. These factors make it politically difficult to open new landfills. Landfills are regulated by state and local governments and must meet minimum requirements set by the United States **Environmental Protection Agency** (EPA). Some household hazardous wastes such as paint, used motor oil, or insecticides can not be accepted at landfills and must be handled separately.

Incineration (burning) of solid waste offers an alternative to disposal in landfills. Incineration converts large amounts of solid waste to smaller amounts of ash. The ash must still be disposed of, however, and it can contain toxic materials. Incineration released **smoke** and other possible pollutants into the air. However, modern incinerators are equipped with smokestack **scrubbers** that are quite effective

in trapping toxic emissions. Many incinerators have the added benefit of generating electricity from the trash they burn.

Composting is a viable alternative to landfills and incineration for some **biodegradable** solid waste. Vegetable trimmings, leaves, grass clippings, straw, horse manure, wood chippings, and similar plant materials are all biodegradable and can be composted. Compost helps the environment because it reduces the amount of waste going into landfills. Correct composting also breaks down biodegradable material into a nutrient-rich soil additive that can be used in gardens or for landscaping. In this way, nutrients vital to plants are returned to the environment. To successfully compost biodegradable wastes, the process must generate high enough temperatures to kill seeds or organisms in the composted material. If done incorrectly, compost piles can give off foul odors.

Families and communities can help reduce household waste by making some simple lifestyle changes. They can reduce solid waste by recycling, repairing rather than replacing durable goods, buying products with minimal packaging, and choosing packaging made from recycled materials. Reducing packaging material is an example of source reduction. Much of the responsibility for source reduction with manufacturers. Businesses need to be encouraged to find smart and cost effective ways to manufacture and package goods in order to minimize waste and reduce the toxicity of the waste created. Consumers can help by encouraging companies to create more environmentally responsible packaging through their choice of products. For example, consumers successfully pressured McDonalds to change from serving their sandwiches in non-biodegradable Styrofoam boxes to wrapping them in biodegradable paper.

For individual households can reduce the amount of waste they send to landfills by recycling. Paper, **aluminum**, glass, and plastic containers are the most commonly recycled household materials. Strategies for household recycling vary from community to community. In some areas materials must separated by type before collection. In others, the separation occurs after collection.

Recycling preserves natural resources by providing an alternative supply of raw materials to industries. It also saves energy and eliminates the emissions of many toxic gases and water pollutants. In addition, recycling helps create jobs, stimulates development of more environmentally sound technologies, and conserves resources for **future generations**. For recycling to be successful, there must be an end market for goods made from recycled materials. Consumers can support recycling by buying "green" products made of recycled materials.

Battery recycling is also becoming increasingly common in the United States and is required by law in many European countries. In 2001, a nonprofit organization called Rechargeable Battery Recycling Corporation (RBRC) began offering American communities cost-free recycling of portable rechargeable batteries such as those used in cell phones, camcorders, and laptop computers. These batteries contain **cadmium**, which is recycled back into other batteries or used in certain coatings or color pigments.

Household waste disposal is an international problem that is being attacked in many ways in many countries. In Tripoli, Libya, a plant exploits household waste, converting it to organic **fertilizer**. The plant recycles 500 tons of household waste, producing 212 tons of fertilizer a day. In France, a country with less available space for landfills than the United States, incineration is proving a desirable alternative. The French are turning household waste into energy through **combustion** and are developing technologies to control the residues that occur from incineration.

In the United States, education of consumers is a key to reducing the volume and toxicity of household waste. The EPA promotes four basic principles for reducing solid waste: reduce the amount of trash discarded, **reuse** products and containers, recycle and compost, and reconsider activities that produce waste.

Hubbard Brook Experimental Forest

The Hubbard Brook Experimental Forest is located in West Thornton, New Hampshire. It is an experimental area established in 1955 within the White Mountains **National Forest** in New Hamphire's central plateau and is administered by the U.S. **Forest Service**. Hubbard Brook was the site of many important ecological studies beginning in the 1960s which established the extent of **nutrient** losses when all the trees in a **watershed** are cut.

Hubbard Brook is a north temperate watershed covered with a mature forest, and it is still accumulating **bio-**

mass. In one early study, vegetation cut in a section of Hubbard Brook was left to decay while nutrient losses were monitored in the **runoff**. Total **nitrogen** losses in the first year were twice the amount cycled in the system during a normal year. With the rise of nitrate in the runoff, concentrations of calcium, magnesium, sodium, and potassium rose. These increases caused eutrophication and **pollution** of the streams fed by this watershed. Once the higher plants had been destroyed, the **soil** was unable to retain nutrients.

Early evidence from the studies indicated that total losses in the **ecosystem** due to the **clear-cutting** were a large number of the total inventory of **species**. The site's ability to support complex living systems was reduced. The lost nutrients could accumulate again, but **erosion** of primary minerals would limit the number of plants and animals sustained in the area.

Another study at the Hubbard Brook site investigated the effects of forest cutting and **herbicide** treatment on nutrients in the forest. All of the vegetation in one of Hubbard Brook's seven watersheds was cut and then the area was treated with the herbicides. At the time the conclusions were startling: **deforestation** resulted in much larger runoffs into the streams. The **pH** of the **drainage** stream went from 5.1 to 4.3, along with a change in temperature and electrical conductivity of the stream water. A combination of higher nutrient concentration, higher water temperature, and greater solar radiation due to the loss of forest cover produced an **algal bloom**, the first sign of eutrophication. This signaled that a change in the ecosystem of the watershed had occurred. It was ultimately demonstrated at Hubbard Brook that the use of herbicides on a cut area resulted in their transfer to the outgoing water.

Hubbard Brook Experimental Forest continues to be an active research facility for foresters and biologists. Most current research focuses on **water quality** and nutrient exchange. The Forest Service also maintians an **acid rain** monitoring station, and conducts research on old-growth forests. The results from various studies done at Hubbard Brook have shown that mature forest ecosystems have a greater ability to trap and store nutrients for **recycling** within the ecosystem. In addition, mature forests offer a higher degrees of **biodiversity** than do forests that are clear-cut. *See also* Aquatic chemistry; Cultural eutrophication; Decline spiral; Experimental Lakes Area; Nitrogen cyle

Hudson River

Starting at Lake Tear of the Clouds, a two-acre (0.8-ha) pond in New York's **Adirondack Mountains**, the Hudson River runs 315 miles (507 km) to the Battery on Manhattan Island's southern tip, where it meets the Atlantic Ocean. Although polluted and extensively dammed for hydroelectric power, the river still contains a wealth of aquatic **species**, including massive sea sturgeon (*Acipenser oxyrhynchus*) and short-nosed sturgeon (*A. brevirostrum*). The upper Hudson is fast-flowing trout stream, but below the Adirondack Forest Preserve, **pollution** from municipal sources, paper companies, and industries degrades the water. Stretches of the upper Hudson contain so-called warm water fish, including northern pike (*Esox lucius*), chain pickerel (*E. niger*), smallmouth bass (*Micropterus dolomieui*), and largemouth bass (*M. salmoides*). These latter two fish swam into the Hudson through the **Lake Erie** and Lake Champlain canals, which were completed in the early nineteenth century.

The Catskill Mountains dominate the mid-Hudson region, which is rich in fish and **wildlife**, though dairy farming, a source of **runoff** pollution, is strong in the region. American shad (*Alosa sapidissima*), historically the Hudson's most important commercial fish, spawn on the river flats between Kingston and Coxsackie. Marshes in this region support snapping turtles (*Chelydra serpentina*) and, in the winter, muskrat (*Ondatra zibethicus*) and mink (*Mustela vison*). Water chestnuts (*Trapa natans*) grow luxuriantly in this section of the river.

Deep and partly bordered by mountains, the lower Hudson resembles a fiord. The unusually deep lower river makes it suitable for navigation by ocean-going vessels for 150 miles (241 km) upriver to Albany. Because the river's surface elevation does not drop between Albany and Manhattan, the tidal effects of the ocean are felt all the way upriver to the Federal Lock and Dam above Albany. These powerful tides make long stretches of the lower Hudson saline or **brackish**, with saltwater penetrating as high as 60 miles (97 km) upstream from the Battery.

The Hudson contains a great variety of botanical species. Over a dozen oaks thrive along its banks, including red oaks (*Quercus rubra*), black oaks (*Q. velutina*), pin oaks (*Q. palustris*), and rock chestnut (*Q. prinus*). Numerous other trees also abound, from mountain laurel (*Kalmia latifolia*) and red pine (*Pinus resinosa*) to flowering dogwood (*Cornus*

florida), together with a wide variety of small herbaceous plants.

The Hudson River is comparatively short. More than 80 American rivers are longer than it, but it plays a major role in New York's economy and **ecology**. Pollution threats to the river have been caused by the **discharge** of industrial and municipal waste, as well as pesticides washed off the land by rain. From 1930 to 1975, one chemical company on the river manufactured approximately 1.4 billion pounds of **polychlorinated biphenyls** (PCBs), and an estimated 10 million pounds a year entered the **environment**. In all, a total of 1.3 million pounds of PCB contamination allegedly occurred during the years prior to the ban, with the pollution originating from plants at Ford Edward and Hudson Falls. A ban was put in place for a time prohibiting the possession, removal, and eating of fish from the waters of the upper Hudson River. A proposed cleanup was designated, to proceed by means of a 40-mile **dredging** and sifting of 2.65 million cubic yards of **sediment** north of Albany, with an anticipated yield of 75 tons of PCBs.

In February of 2001 the U.S. **Environmental Protection Agency** (EPA), having invoked the Superfund law, required the chemical company to begin planning the cleanup. The company was given several weeks to present a viable plan of attack, or else face a potential $1.5 billion fine for ignoring the directive in lieu of the cost of cleanup. The cleanup cost, estimated at $500 million was presented as the preferred alternative. The engineering phase of the cleanup project was expected to take three years of planning and was to be scheduled after the offending company filed a response to the EPA. The company responded within the allotted time frame in order to placate the EPA, although the specifics of a drafted work plan remained undetermined, and the company refused to withdraw a lawsuit filed in November of 2000, which challenged the constitutionality of the so-called Superfund law that authorized the EPA to take action. The river meanwhile was ranked by one environmental watchdog group as the fourth most endangered in the United States, specifically because of the PCB contamination. Environmental groups demanded also that attention be paid to the issues of **urban sprawl**, noise, and other pollution, while proposals for potentially polluting projects were endorsed by industrialists as a means of spurring the area's economy. Among these industrial projects, the construction of a cement plant in Catskill where there is easy access to a limestone quarry, and the development of a power plant along the river in Athens generated controversy, stemming from the industrial asset afforded by development along the river versus the advantages of a less fouled environment. Additionally, the power plant, which threatened to add four new smokestacks to the skyline and to aggravate pollution, was seen as potentially detrimental to tourism in that area. Also in recent decades, **chlorinated hydrocarbons**, dieldrin, endrin, DDT, and other pollutants have been linked to the decline in populations of the once common Jefferson salamander (*Ambystoma jeffersonianum*), fish hawk (*Pandion haliaetus*), and **bald eagle** (*Haliaeetus leucocephalus*).

Concerns over the condition of the lower river spread anew following a severe September 11 terrorist attack on New York City in 2001. In this coastal tri-state urban area where anti-dumping laws were put in place in the mid twentieth century to protect the river from deterioration due to pollution, new threats of pollution surfaced regarding the potential for assorted types of leakage into the river caused when the integrity of some land-based structures including seawalls and underwater tunnels was compromised by the impact of exploding commercial jetliners involved in the attack. *See also* Agricultural pollution; Dams; Estuary; Feedlot runoff; Fertilizer runoff; Industrial waste treatment; Sewage treatment; Wastewater

Human ecology

Human **ecology** may be defined as the branch of knowledge concerned with relationships between human beings and their environments. Among the disciplines contributing seminal work in this field are sociology, anthropology, geography, economics, psychology, political science, philosophy, and the arts. Applied human ecology emerges in engineering, planning, architecture, landscape architecture, **conservation**, and public health. Human ecology, then, is an interdisciplinary study which applies the principles and concepts of ecology to human problems and the human condition. The notion of interaction—between human beings and the **environment** and between human beings—is fundamental to human ecology, as it is to biological ecology.

Human ecology as an academic inquiry has disciplinary roots extending back as far as the 1920s. However, much work in the decades prior to the 1970s was narrowly drawn and was often carried out by a few individuals whose intellectual legacy remained isolated from the mainstream of their

disciplines. The work done in sociology offers an exception to the latter (but not the former) rule; sociological human ecology is traced to the Chicago school and the intellectual lineage of Robert Ezra Park, his student Roderick D. Mackenzie, and Mackenzie's student Amos Hawley. Through the influence of these men and their school, human ecology, for a time, was narrowly identified with a sociological analysis of spatial patterns in urban settings (although broader questions were sometimes contemplated).

Comprehensive treatment of human ecology is first found in the work of Gerald L. Young, who pioneered the study of human ecology as an interdisciplinary field and as a conceptual framework. Young's definitive framework is founded upon four central themes. The first of these is interaction, and the other three are developed from it: levels of organization, functionalism (part-whole relationships), and holism. These four basic concepts form the foundation for a series of field derivatives (**niche**, community, and **ecosystem**) and consequent notions (institutions, proxemics, alienation, ethics, world community, and stress/capacitance). Young's emphasis on linkages and process set his approach apart from other synthetic attempts in human ecology, which were largely cumbersome classificatory schemata. These were subject to harsh criticism because they tended to embrace virtually all knowledge, resolve themselves into superficial lists and mnemonic "building blocks," and had little applicability to real-world problems.

Generally, comprehensive treatment of human ecology is more advanced in Europe than it is in the United States. A comprehensive approach to human ecology as an interdisciplinary field and conceptual framework gathered momentum in several independent centers during the 1970s and 1980s. Among these have been several college and university programs and research centers, including those at the University of Göteborg, Sweden, and, in the United States, at Rutgers University and the University of California at Davis. Interdisciplinary programs at the undergraduate level were first offered in 1972 by the College of the Atlantic (Maine) and The Evergreen State College (Washington). The Commonwealth Human Ecology Council in the United Kingdom, the International Union of Anthropological and Ethnological Sciences' Commission on Human Ecology, the Centre for Human Ecology at the University of Edinburgh, the Institute for Human Ecology in California, and professional societies and organizations in Europe and the United States have been other centers of development for the field.

Dr. Thomas Dietz, President of the Society for Human Ecology, defined some of the priority research problems which human ecology addresses in recent testimony before the U.S. House of Representatives Subcommittee on Environment and the **National Academy of Sciences** Committee on Environmental Research. Among these, Dietz listed global change, values, post-hoc evaluation, and science and conflict in **environmental policy**. Other human ecologists would include in the list such items as commons problems, **carrying capacity**, **sustainable development**, human health, ecological economics, problems of resource use and distribution, and family systems. Problems of epistemology or cognition such as environmental perception, consciousness, or paradigm change also receive attention.

Our Common Future, the report of the United Nation's World Commission on Environment and Development of 1987, has stimulated a new phase in the development of human ecology. A host of new programs, plans, conferences and agendas have been put forth, primarily to address phenomena of global change and the challenge of sustainable development. These include the *Sustainable Biosphere Initiative* published by the **Ecological Society of America** in 1991 and extended internationally; the United Nations Conference on Environment and Development; the proposed new United States National Institutes for the Environment; the Man and the **Biosphere** Program's Human-Dominated Systems Program; the report of the **National Research Council** Committee on Human Dimensions of Global Change and the associated National Science Foundation's Human Dimensions of Global Change Program; and **green plans** published by the governments of Canada, Norway, the Netherlands, the United Kingdom, and Austria. All of these programs call for an integrated, interdisciplinary approach to complex problems of human-environmental relationships. The next challenge for human ecology will be to digest and steer these new efforts and to identify the perspectives and tools they supply.

Humane Society of the United States

The largest animal protection organization in the United States, Humane Society of the United States (HSUS) works

to preserve **wildlife** and **wilderness**, save **endangered species**, and promote humane treatment of all animals. Formed in 1954, HSUS specializes in education, cruelty investigations and prosecutions, wildlife and **nature** preservation, environmental protection, federal and state legislative activities, and other actions designed to protect animal welfare and the **environment**.

Major projects undertaken by HSUS in recent years have included campaigns to stop the killing of **whales**, **dolphins**, **elephants**, bears, and **wolves**; to help reduce the number of animals used in medical research and to improve the conditions under which they are used; to oppose the use of fur by the fashion industry; and to address the problem of pet overpopulation.

The group has worked extensively to ban the use of tuna caught in a way that kills dolphins, largely eliminating the sale of such products in the United States and western Europe. It has tried to stop international airlines from transporting exotic birds into the United States. Other high priority projects have included banning the international trade in elephant ivory, especially imports into the United States, and securing and maintaining a general worldwide moratorium on commercial **whaling**.

HSUS companion animals section works on a variety of issues affecting dogs, cats, birds, horses, and other animals commonly kept as pets, striving to promote responsible pet ownership, particularly the spaying and neutering of dogs and cats to reduce the tremendous overpopulation of these animals. HSUS works closely with local shelters and humane societies across the country, providing information, training, evaluation, and consultation.

Several national and international environmental and animal protection groups are affiliated and work closely with HSUS. Humane Society International works abroad to fulfill HSUS's mission and to institute reform and educational programs that will benefit animals. EarthKind, a global environmental protection group that emphasizes wildlife protection and humane treatment of animals, has been active in Russia, India, Thailand, Sri Lanka, the United Kingdom, Romania, and elsewhere, working to preserve forests, **wetlands**, wild rivers, natural ecosystems, and endangered wildlife.

The National Association for Humane and **Environmental Education** is the youth education division of HSUS, developing and producing periodicals and teaching materials designed to instill humane values in students and young people, including *KIND (Kids in Nature's Defense) News*, a newspaper for elementary school children, and *KIND TEACHER*, an 80-page annual full of worksheets and activities for use by teachers.

The Center for Respect of Life and the Environment works with academic institutions, scholars, religious leaders and organizations, arts groups, and others to foster an ethic of respect and compassion towards all creatures and the natural environment. Its quarterly publication, *Earth Ethics*, examines such issues as earth education, sustainable communities, ecological economics, and other values affecting our relationship with the natural world. The Interfaith Council for the Protection of Animals and Nature promotes **conservation** and education mainly within the religious community, attempting to make religious leaders, groups, and individuals more aware of our moral and spiritual obligations to preserve the planet and its myriad life forms.

HSUS has been quite active, hard-hitting, and effective in promoting its animal protection programs, such as leading the fight against the fur industry. It accomplishes its goals through education, lobbying, grassroots organizing, and other traditional, legal means of influencing public opinion and government policies.

With over 3.5 million members or "constituents" and an annual budget of over $35 million, HSUS is considered the largest and one of the most influential animal protection groups in the United States and, perhaps, the world.

Humanism

A perspective or doctrine that focuses primarily on the interests, capacities, and achievements of human beings. This focus on human concerns has led some to conclude that human beings have rightful dominion over the earth and that their interests and well-being are paramount and take precedence over all other considerations. *Religious humanism*, for instance, generally holds that God made human beings in His own image and put them in charge of His creation. *Secular humanism* views human beings as the source of all value or worth. Some environmentally-minded critics, such as Lynn White Jr., and David Ehrenfeld claim that much environmental destruction can be traced to "the arrogance of humanism."

Human-powered vehicles

Finding easy modes of **transportation** seems to be a basic human need, but finding easy *and clean* modes is becoming imperative. Traffic congestion, overconsumption of **fossil fuels** and **air pollution** are all direct results of automotive

Innovative bicycle designs. (McGraw-Hill Inc. Reproduced by permission.)

lifestyles around the world. The logical alternative is human-powered vehicles (HPVs), perhaps best exemplified in the bicycle, the most basic HPV. New high-tech developments in HPVs are not yet ready for mass production, nor are they able to compete with cars. Pedal-propelled HPVs in the air, on land, or under the sea are still in the expensive, design-and-race-for-a-prize category. But the challenge of human-powered transport has inspired a lot of inventive thinking, both amateur and professional.

Bicycles and rickshaws comprise the most basic HPVs. Of these two vehicles, bicycles are clearly the most popular, and production of these HPVs has surpassed production of automobiles in recent years. The number of bicycles in use throughout the world is roughly double that of cars; China alone contains 270 million bicycles, or one third of the total bicycles worldwide. Indeed the bicycle has overtaken the **automobile** as the preferred mode of transportation in many nations. There are many reasons for the popularity of the bike: it fulfills both recreational and functional needs, it is an economical alternative to automobiles, and it does not contribute to the problems facing the **environment**.

Although the bicycle provides a healthy and scenic form of **recreation**, people also find it useful in basic transportation. In the Netherlands, bicycle transportation accounts for 30% of work trips and 60% of school trips. One-third of commuting to work in Denmark is by bicycle. In China, the vast majority of all trips there are made via bicycle.

A surge in bicycle production occurred in 1973, when in conjunction with rising oil costs, production doubled to 52 million per year. Soaring fuel prices in the 1970s inspired people to find inexpensive, economical alternatives to cars, and many turned to bicycles. Besides being efficient transportation, bikes are simply cheaper to purchase and to maintain than cars. There is no need to pay for parking or tolls, no expensive upkeep, and no high fuel costs.

The lack of fuel costs associated with bicycles leads to another benefit: bicycles do not harm the environment. Cars consume fossil fuels and in so doing release more than two-thirds of the United States' smog-producing **chemicals**. They are furthermore considered responsible for many other environmental ailments: depletion of the **ozone** layer

through release of **chlorofluorocarbons** from automobile air conditioning units; cause of **cancer** through toxic emissions; and consumption of the world's limited fuel resources. With human energy as their only requirement, bicycles have none of these liabilities.

Nevertheless, in many cases—such as long trips or travelling in inclement weather—cars are the preferred form of transportation. Bicycles are not the optimal choice in many situations. Thus engineers and designers seek to improve on the bicycle and make machines suitable for transport under many different conditions. They are striving to produce new human-powered vehicles—HPVs that maximize air and sea currents, that have reasonable interior ergonomics, and that can be inexpensively produced. Several machines designed to fit this criteria exist.

As for developments in human-powered aircraft, success is judged on distance and speed, which depend on the strength of the pedaller and the lightness of the craft. The current world record holder is Greek Olympic cyclist Kanellos Kanellopoulos who flew *Daedalus 88*. *Daedalus 88* was created by engineer John Langford and a team of MIT engineers and funded by American corporations. Kanellopoulos flew *Daedalus 88* for 3 hours and 54 minutes across the Aegean Sea between Crete and Santorini, a distance of 74 mi (119 km), in April 1988. The craft averaged 18.5 mph (29 kph) and flew 15 ft (4.6 m) above the water. Upon arrival at Santorini, however, the sun began to heat up the black sands and generate erratic shore winds and *Daedalus 88* plunged into the sea. It was a few yards short of its goal, and the tailboom of the 70-lb (32-kg) vehicle was snapped by the wind. But to cheering crowds on the beach, Kanellopoulos rose from the sea with a victory sign and strode to shore.

In the creation of a human-powered helicopter, students at California Polytechnic State University had been working on perfecting one since 1981. In 1989 they achieved liftoff with Greg McNeil, a member of the United States National Cycling Team, pedalling an astounding 1.0 hp. The graphite epoxy, wood, and Mylar craft, *Da Vinci III*, rose 7 in (17.7 cm) for 6.8 seconds. But rules for the $10,000 Sikorsky prize, sponsored by the American Helicopter Society, stipulate that the winning craft must rise nearly 10 ft, or 3 m, and stay aloft one minute.

On land, recumbent vehicles, or recumbents, are wheeled vehicles in which the driver pedals in a semi-recumbent position, contained within a windowed enclosure. The world record was set in 1989 by American Fred Markham at the Michigan International Speedway in an HPV named *Goldrush*. Markham pedalled more than 44 mph (72 kph).

Unfortunately, the realities of road travel cast a long shadow over recumbent HPVs. Crews discovered that they tended to be unstable in crosswinds, distracted other drivers and pedestrians, and lacked the speed to correct course safely in the face of oncoming cars and trucks.

In the sea, being able to maneuver at your own pace and be in control of your vehicle—as well as being able to beat a fast retreat undersea—are the problems faced by HPV submersible engineers. Human-powered subs are not a new idea. The Revolutionary War created a need for a bubble sub that was to plant an explosive in the belly of a British ship in New York Harbor. (The naval officer, breathing one-half hour's worth of air, failed in his night mission, but survived).

The special design problems of modern two-person HP-subs involve controlling buoyancy and ballast, pitch and yaw (nose up/down/sideways), reducing drag, increasing thrust, and positioning the pedaller and the propulsor in the flooded cockpit (called "wet") in ways that maximize air intake from scuba tanks and muscle power from arms and legs.

Depending on the design, the humans in HP-subs lie prone, foot to head or side by side, or sit, using their feet to pedal and their hands to control the rudder through the underwater currents. Studies by the United States Navy Experimental Dive Unit indicate that a well-trained athlete can sustain 0.5 hp for 10 minutes underwater.

On the surface of the water, fin-propelled watercraft—lightweight inflatables that are powered by humans kicking with fins—are ideal for fishermen whom maneuverability, not speed, is the goal. Paddling with the legs, which does not disturb fish, leaves the hands free to cast. In most designs, the fisherman sits on a platform between tubes, his feet in the water. Controllability is another matter, however: in open windy water, the craft is at the mercy of the elements in its current design state. Top speed is about 50 yd (46 m) in three minutes.

Finally, over the surface of the water, the first human-powered hydrofoil, *Flying Fish*, with national track sprinter Bobby Livingston, broke a world record in September 1989 when it traveled 100 m over Lake Adrian, Michigan, at 16.1 knots (18.5 mph). A vehicle that pedalled like a bicycle, resembled a model airplane with a two-blade propeller and a 6-ft (1.8-m) **carbon** graphite wing, *Flying Fish* sped across the surface of the lake on two pontoons.

Humus

Humus is essentially decomposed organic matter in **soil**. Humus can vary in color but is often dark brown. Besides containing valuable nutrients, there are many other benefits of humus: it stabilizes soil mineral particles into aggregates, improves pore space relationships and aids in air and water movement, aids in water holding capacity, and influences the **absorption** of **hydrogen** ions as a **pH** regulator.

Hunting and trapping

Wild animals are a potentially renewable natural resource. This means that they can be harvested in a sustainable fashion, as long as then birth rate is greater than the rate of exploitation by humans. In the sense meant here, "harvesting" refers to the killing of wild animals as a source of meat, fur, antlers, or other useful products, or as an outdoor sport. The harvesting can involve trapping, or hunting using guns, bows-and-arrows, or other weapons. (Fishing is also a kind of hunting, but it is not dealt with here). From the ecological perspective, it is critical that the exploitation is undertaken in a sustainable fashion; otherwise, serious damages are caused to the resource and to ecosystems more generally.

Unfortunately, there have been numerous examples in which wild animals have been harvested at grossly unsustainable rates, which caused their populations to decline severely. In a few cases this caused **species** to become extinct—they no longer occur anywhere on Earth. For example, commercial hunting in North America resulted in the extinctions of the great auk (*Pinguinnis impennis*), **passenger pigeon** (*Ectopistes migratorius*), and Steller's sea cow (*Hydrodamalis stelleri*). Unsustainable commercial hunting also brought other species to the brink of **extinction**, including the Eskimo curlew (*Numenius borealis*), northern right whale (*Eubalaena glacialis*), northern fur seal (*Callorhinus ursinus*), grey whale (*Eschrichtius robustus*), and American **bison** or buffalo (*Bison bison*).

Fortunately, these and many other examples of overexploitation of wild animals by humans are regrettable cases from the past. Today, the exploitation of wild animals in North America is undertaken with a view to the longer-term **conservation** of their stocks, that is, an attempt is made to manage the harvesting in a sustainable fashion. This means that trapping and hunting are much more closely regulated than they used to be.

If harvests of wild animals are to be undertaken in a sustainable manner, it is critical that harvest levels are determined using the best available understanding of population-level productivity and stock sizes. It is also essential that harvest quotas are respected by trappers and hunters and that illegal exploitation (or **poaching**) does not compromise what might otherwise be a sustainable activity. The challenge of modern **wildlife management** is to ensure that good conservation science is sensibly integrated with effective monitoring and management of the rates of exploitation.

Ethics of trapping and hunting

From the strictly ecological perspective, sustainable trapping and hunting of wild animals is no more objectionable than the prudent harvesting of timber or agricultural crops. However, people have widely divergent attitudes about the killing of wild (or domestic) animals for meat, sport, or profit. At one end of the ethical spectrum are people who see no problem with the killing wild animals as a source of meat or cash. At the other extreme are individuals with a profound respect for the rights of all animals, and who believe that killing any sentient creature is ethically wrong. Many of these latter people are animal-rights activists, and some of them are involved in organizations that undertake high-profile protests and other forms of advocacy to prevent or restrict trapping and hunting. In essence, these people object to the lethal exploitation of wild animals, even under closely regulated conditions that would not deplete their populations. Most people, of course, have attitudes that are intermediate to those just described.

Trapping

The fur trade was one a very important commercial activity during the initial phase of the colonization of North America by Europeans. During those times, as now, furs were a valuable commodity that could be obtained from **nature** and could be sold at a great profit in urban markets. In fact, the quest for furs was the most important reason for much of the early exploration of the interior of North America, as fur traders penetrated all of the continent's great rivers seeking new sources of pelts and profit. Most fur-bearing animals are harvested by a form of hunting known as trapping.

Until recently, most trapping involved leg-hold traps, a relatively crude method that results in many animals enduring cruel and lingering deaths. Fortunately, other, more humane alternatives now exist in which most trapped animals are killed quickly and do not suffer unnecessarily. In large part, the movement towards more merciful trapping methods has occurred in response to effective, high-profile lobbying by organizations that oppose trapping, and the trapping industry has responded by developing and using more humane methods of killing wild furbearers.

Various species of furbearers are trapped in North America, particularly in relatively remote, wild areas, such as the northern and montane forests of the continental United States, Alaska, and Canada. Among the most valuable furbearing species are beaver (*Castor canadensis*), muskrat (*Ondatra zibethicus*), mink (*Mustela vison*), river otter (*Enhydra lutris*), bobcat (*Lynx rufus*), lynx (*Lynx canadensis*), red fox (*Vulpes vulpes*), wolf (*Canis lupus*), and **coyote** (*Canis latrans*). The hides of other species are also valuable, such as black bear (*Ursus americanus*), white-tailed deer (*Odocoileus virginianus*), and moose (*Alces alces*), but these species are not hunted primarily for their pelage.

Some species of **seals** are hunted for their fur, although this is largely done by shooting, clubbing, or netting, rather than by trapping. The best examples of this are the harp seal (*Phoca groenlandica*) of the northwestern Atlantic Ocean and the northern fur seal (*Callorhinus ursinus*) of the Bering Sea. Many seal pups are killed by commercial hunters in the spring when their coats are still white and soft. This harvest has been highly controversial and is the subject of intense opposition from **animal rights** groups.

Game Mammals

Hunting is a popular sport in North America, enjoyed by about 16 million people each year, most of them men. In 1991, hunting contributed more than $12 billion to the United States economy, about half of which was spent by big-game hunters.

Various species of terrestrial animals are hunted in large numbers. This is mostly done by stalking the animals and shooting them with rifles, although shotguns and bow-and-arrow are sometimes used. Some hunting is done for subsistence purposes, that is, the meat of the animals is used to feed the family or friends of the hunters. Subsistence hunting is especially important in remote areas and for aboriginal hunters. Commercial or market hunts also used to be common, but these are no longer legal in North America (except under exceptional circumstances) because they have generally proven to be unsustainable. However, illegal, semi-commercial hunting (or poaching) still takes place in many remote areas where game animals are relatively abundant and where there are local markets for wild meat.

In addition, many people hunt as a sport, that is, for the excitement and accomplishment of tracking and killing wild animals. In such cases, using the meat of the hunted animals may be only a secondary consideration, and in fact the hunter may only seek to retain the head, antlers, or horns of the prey as a trophy (although the meat may be kept by the hunter's guide). Big-game hunting is an economically important activity in North America, with large amounts of money being spent on the equipment, guides, and **transportation** necessary to undertake this sport.

The most commonly hunted big-game mammal in North America is the white-tailed deer. Other frequently hunted ungulates include the mule deer (*Odocoileus hemionus*), moose, elk or wapiti (*Cervus canadensis*), caribou (*Rangifer tarandus*), and pronghorn antelope (*Antilocapra americana*). Black bear and **grizzly bear** (*Ursus arctos*) are also hunted, as are bighorn sheep (*Ovis canadensis*) and mountain goat (*Oreamnos americanus*). Commonly hunted small-game species include various species of rabbits and hares, such as the cottontail rabbit (*Sylvilagus floridanus*), snowshoe hare (*Lepus americanus*), and jackrabbit (*Lepus californicus*), as well as the grey or black squirrel (*Sciurus carolinensis*) and woodchuck (*Marmota monax*). Wild boar (*Sus scrofa*) are also hunted in some regions—these are feral animals descended from escaped domestic pigs.

Game birds

Various larger species of birds are hunted in North America for their meat and for sport. So-called upland game birds are hunted in terrestrial habitats and include ruffed grouse (*Bonasa umbellus*), willow ptarmigan (*Lagopus lagopus*), bobwhite quail (*Colinus virginianus*), wild turkey (*Meleagris gallopava*), mourning dove (*Zanaidura macroura*), and woodcock (*Philohela minor*). Several **introduced species** of upland gamebirds are also commonly hunted, particularly ring-necked pheasant (*Phasianus colchicus*) and Hungarian or grey partridge (*Perdix perdix*).

Much larger numbers of waterfowl are hunted in North America, including millions of ducks and geese. The most commonly harvested species of waterfowl are mallard (*Anas platyrhynchos*), wood duck (*Aix sponsa*), Canada goose (*Branta canadensis*), and snow and blue goose (*Chen hyperborea*), but another 35 or so species in the duck family are also hunted. Other hunted waterfowl include coots (*Fulica americana*) and moorhens (*Gallinula chloropus*).

Hurricane

Hurricanes, called typhoons or tropical cyclones in the Far East, are intense cyclonic storms which form over warm tropical waters, and generally remain active and strong only while over the oceans. Their intensity is marked by a distinct spiraling pattern of clouds, very low atmospheric pressure at the center, and extremely strong winds blowing at speeds greater than 74 mph (120 kph) within the inner rings of clouds. Typically when hurricanes strike land and move inland, they immediately start to disintegrate, though before they do they bring widespread destruction of property and loss of life. The radius of such a storm can be 100 mi (160 km) or greater. Thunderstorms, hail, and tornados frequently are imbedded in hurricanes.

Hurricanes occur in every tropical ocean except the South Atlantic, and with greater frequency from August through October than any other time of year. The center of a hurricane is called the eye. It is an area of relative calm, few clouds and higher temperatures, and represents the center of the low pressure pattern. Hurricanes usually move from east to west near the tropics, but when they migrate poleward to the mid-latitudes they can get caught up in the general west to east flow pattern found in that region of the earth. *See also* Tornado and cyclone

George Evelyn Hutchinson (1903 – 1991)

American ecologist

Born January 30, 1903, in Cambridge, England, Hutchinson was the son of Arthur Hutchinson, a professor of mineralogy at Cambridge University, and Evaline Demeny Shipley Hutchinson, an ardent feminist. He demonstrated an early interest in **flora** and **fauna** and a basic understanding of the scientific method. In 1918, at the age of 15, he wrote a letter to the *Entomological Record and Journal of Variation* about a grasshopper he had seen swimming in a pond. He described an experiment he performed on the insect and included it for taxonomic identification.

In 1924, Hutchinson earned his bachelor's degree in zoology from Emmanuel College at Cambridge University, where he was a founding member of the Biological Tea Club. He then served as an international education fellow at the Stazione Zoologica in Naples from 1925 until 1926, when he was hired as a senior lecturer at the University of Witwatersrand in Johannesburg, South Africa. He was apparently fired from this position two years later by administrators who never imagined that in 1977 the university would honor the ecologist by establishing a research laboratory in his name.

Hutchinson earned his master's degree from Emmanuel College *in absentia* in 1928 and applied to Yale University for a fellowship so he could pursue a doctoral degree. He was instead appointed to the faculty as a zoology instructor. He was promoted to assistant professor in 1931 and became an associate professor in 1941, the year he obtained his United States citizenship. He was made a full professor of zoology in 1945, and between 1947 and 1965 he served as director of graduate studies in zoology. Hutchinson never did receive his doctoral degree, though he amassed an impressive collection of honorary degrees during his lifetime.

Hutchinson was best known for his interest in **limnology**, the science of freshwater lakes and ponds. He spent most of his life writing the four-volume *Treatise on Limnology*, which he completed just months before his death. The research that led to the first volume—covering geography, physics, and chemistry—earned him a Guggenheim Fellowship in 1957. The second volume, published in 1967, covered biology and **plankton**. The third volume, on water plants, was published in 1975, and the fourth volume, about invertebrates, appeared posthumously in 1993.

The *Treatise on Limnology* was among the nine books, nearly 150 research papers, and many opinion columns which Hutchinson penned. He was an influential writer whose scientific papers inspired many students to specialize in **ecology**. Hutchinson's greatest contribution to the science of ecology was his broad approach, which became known as the "Hutchinson school." His work encompassed disciplines as varied as biochemistry, geology, zoology, and botany. He pioneered the concept of **biogeochemistry**, which examines the exchange of **chemicals** between organisms and the **environment**. His studies in biogeochemistry focused on how **phosphates** and **nitrates** move from the earth to plants, then animals, and then back to the earth in a continuous cycle. His **holistic approach** influenced later environmentalists when they began to consider the global scope of environmental problems.

In 1957, Hutchinson published an article entitled "Concluding Remarks," considered his most inspiring and intriguing work, as part of the Cold Spring Harbor Symposia on Quantitative Biology. Here, he introduced and described

the ecological **niche**, a concept which has been the source of much research and debate ever since. The article was one of only three in the field of ecology chosen for the 1991 collection *Classics in Theoretical Biology.*

Hutchinson won numerous major awards for his work in ecology. In 1950, he was elected to the National Academy of Science. Five years later, he earned the Leidy Medal from the Philadelphia Academy of Natural Sciences. He was awarded the Naumann Medal from the International Association of Theoretical and Applied Limnology in 1959. This is a global award, granted only once every three years, which Hutchinson earned for his contributions to the study of lakes in the first volume of his treatise. In 1962, the **Ecological Society of America** chose him for its Eminent Ecologist Award.

Hutchinson's research often took him out of the country. In 1932, he joined a Yale expedition to Tibet, where he amassed a vast collection of organisms from high-altitude lakes. He wrote many scientific articles about his work in North India, and the trip also inspired his 1936 travel book, *The Clear Mirror.* Other research projects drew Hutchinson to Italy, where, in the **sediment** of Lago di Monterosi, a lake north of Rome, he found evidence of the first case of artificial eutrophication, dating from around 180 B.C.

Hutchinson was devoted to the arts and humanities, and he counted several musicians, artists, and writers among his friends. The most prominent of his artistic friends was English author Rebecca West. He served as her literary executor, compiling a bibliography of her work which was published in 1957. He was also the curator of a collection of her papers at Yale's Beinecke Library. Hutchinson's writing reflected his diverse interests. Along with his scientific works and his travel book, he also wrote an autobiography and three books of essays, *The Itinerant Ivory Tower* (1953), *The Enchanted Voyage and Other Studies* (1962), and *The Ecological Theatre and the Evolutionary Play* (1965). For 12 years, beginning in 1943, Hutchinson wrote a regular column titled "Marginalia" for the *American Scientist.* His thoughtful columns examined the impact on society of scientific issues of the day.

Hutchinson's skill at writing, as well as his literary interests, was recognized by Yale's literary society, the Elizabethan Club, which twice elected him president. He was also a member of the Connecticut Academy of Arts and Sciences and served as its president in 1946.

While Hutchinson built his reputation on his research and writing, he also was considered an excellent teacher. His teaching career began with a wide range of courses including beginning biology, entomology, and vertebrate embryology. He later added limnology and other graduate courses to his areas of expertise. He was personable as well as innovative, giving his students illustrated note sheets, for example, so they could concentrate on his lectures without worrying about taking their own notes. Leading oceanographer Linsley Pond was among the students whose careers were changed by Hutchinson's teaching. Pond enrolled in Yale's doctoral program with the intention of becoming an experimental embryologist. But after one week in Hutchinson's limnology class, he had decided to do his dissertation research on a pond.

Hutchinson loved Yale. He particularly cherished his fellowship in the residential Saybrook College. He was also very active in several professional associations, including the American Academy of Arts and Sciences, the American Philosophical Society, and the **National Academy of Sciences**. He served as president of the American Society of Limnology and Oceanography in 1947, the American Society of Naturalists in 1958, and the International Association for Theoretical and Applied Limnology from 1962 until 1968.

Hutchinson retired from Yale as professor emeritus in 1971, but continued his writing and research for 20 more years, until just months before his death. He produced several books during this time, including the third volume of his treatise, as well as a textbook titled *An Introduction to Population Ecology* (1978), and memoirs of his early years, *The Kindly Fruits of the Earth* (1979).

He also occasionally returned to his musings on science and society, writing about several topical issues in 1983 for the *American Scientist.* Here, he examined the question of nuclear disarmament, speculating that "it may well be that total nuclear disarmament would remove a significant deterrent to all war." In the same article, he also philosophized on differences in behavior between the sexes: "On the whole, it would seem that, in our present state of **evolution**, the less aggressive, more feminine traits are likely to be of greater value to us, though always endangered by more aggressive, less useful tendencies. Any such sexual difference, small as it may be, is something on which perhaps we can build."

Several of Hutchinson's most prestigious honors, including the Tyler Award, came during his retirement. Hutchinson earned the $50,000 award, often called the Nobel Prize for **conservation**, in 1974. That same year, the National Academy of Sciences gave him the Frederick Garner Cottrell Award for Environmental Quality. He was awarded the Franklin Medal from the Franklin Institute in 1979, the Daniel Giraud Elliot Medal from the National Academy of Sciences in 1984, and the Kyoto Prize in Basic Science from Japan in 1986. Having once rejected a National Medal of Science because it would have been bestowed on him by President Richard Nixon, he was awarded the medal posthumously by President George Bush in 1991.

Hutchinson's first marriage, to Grace Evelyn Pickford, ended with a divorce in 1933. During the six weeks residence

the state of Nevada then required to grant divorces, he studied the lakes near Reno and wrote a major paper on freshwater ecology in **arid** climates. Later that year, Hutchinson married Margaret Seal, who died in 1983 from Alzheimer's disease. Hutchinson cared for her at home during her illness. In 1985, he married Anne Twitty Goldsby, whose care enabled him to travel extensively and continue working in spite of his failing health. When she died unexpectedly in December 1990, the ailing widower returned to his British homeland. He died in London on May 17, 1991, and was buried in Cambridge.

Hybrid vehicles

The roughly 200 million automobiles and light trucks currently in use in the United States travel approximately 2.4 trillion miles every year, and consume almost two-thirds of the U.S. oil supply. They also produce about two-thirds of the **carbon monoxide**, one-third of the **lead** and **nitrogen oxides**, and a quarter of all volatile organic compounds (VOCs). More efficient **transportation** energy use could have dramatic effects on environmental quality as well as saving billions of dollars every year in our payments to foreign governments. In response to high **gasoline** prices in the 1970s and early 1980s, **automobile** gas-mileage averages in the United States more than doubled from 13 mpg in 1975 to 28.8 mpg in 1988.

Unfortunately, cheap fuel prices and the popularity of sport utility vehicles (SUVs) and light trucks in the 1990s caused fuel efficiency to slide back below where it was 25 years earlier. By 2002, the average mileage for U.S. cars and trucks was only 27.6 mpg. Amory B. Lovins of the **Rocky Mountain Institute** in Colorado estimated that raising the average fuel efficiency of the United States car and light truck fleet by one mile per gallon would cut oil consumption about 295,000 barrels per day. In one year, this would equal the total amount the Interior Department hopes to extract from the **Arctic National Wildlife Refuge** (ANWR) in Alaska.

It isn't inevitable that we consume and pollute so much. A number of alternative transportation options already are available. Of course the lowest possible fossil fuel consumption option is to walk, skate, ride a bicycle, or other forms of human-powered movement. Many people, however, want or need the comfort and speed of a motor vehicle. Several models of battery-powered electric automobiles have been built, but the batteries are heavy, expensive, and require more frequent recharging than most customers will accept. Even though 90% of all daily commutes are less than 50 mi (80 km), most people want the capability to take a long road trip of several hundred miles without needing to stop for fuel or recharging.

An alternative that appears to have much more customer appeal is the hybrid gas-electric vehicle. The first hybrid to be marketed in the United States was the two-seat Honda Insight. A 3-cylinder, 1.0 liter gas engine is the main power source for this sleek, lightweight vehicle. A 7-hp (horsepower) electric motor helps during acceleration and hill climbing. When the small battery pack begins to run down, it is recharged by the gas engine, so that the vehicle never needs to be plugged in. More electricity is captured during "regenerative" braking further increasing efficiency. With a streamlined lightweight plastic and **aluminum** body, the Insight gets about 75 mpg (33.7 km/l) in highway driving and has low-enough emissions to qualify as a "super low **emission** vehicle." It meets the most strict **air quality** standards anywhere in the United States. Quick acceleration and nimble handling make the Insight fun to drive. Current cost is about $20,000.

Perhaps the biggest drawback to the Insight is its limited passenger and cargo capacity. Although the vast majority of all motor vehicle trips made in the United States involve only a single driver, most people want the ability to have more than one passenger or several suitcases at least

occasionally. To meet this need, Honda introduced a hybrid-engine version of its popular Civic line in 2002. With four doors and ample space for four adults plus a reasonable amount of luggage. The 5-speed manual version of the Civic hybrid gets 48 mpg in both city and highway driving. With a history of durability and consumer satisfaction in other Honda models, and a 10-year warranty on its battery and drive train, the hybrid Civic appears to offer the security that consumers will want in adopting this new technology.

Toyota also has introduced a hybrid vehicle called the Prius. Similar in size to the Honda Civic, the Prius comes in a four-door model with enough room for the average American family. During most city driving, it depends only on its quiet, emission-free, electric motor. The batteries needed to drive the 40-hp are stacked up behind the back seat providing a surprisingly large trunk for luggage. The 70-hp, 1.5 liter gas engine kicks in to help accelerate or when the batteries need recharging. Getting about 52 mpg (22 km/l) in city driving, the Prius is one of the most efficient cars on the road and can travel more than 625 mi (1,000 km) without refueling. Some drivers are unnerved by the noiseless electric motor. Sitting at a stoplight, it makes no sound at all. You might think it was dead, but when the light changes, you glide off silently and smoothly.

Introduced in Japan in 1997, the Prius sells in the United States for about the same price as the Honda hybrids. The **Sierra Club** estimates that in 100,000 mi (160,000 km), a Prius will generate 27 tons of CO_2, a Ford Taurus will generate 64 tons, while the Ford Excursion SUV will produce 134 tons. In 1999, the Sierra Club awarded both the Insight and the Prius an "excellence in engineering" award, the first time this organization has ever endorsed commercial products.

Both Ford and General Motors (GM) have announced intentions to build hybrid engines for their popular sport utility vehicles and light trucks. This program may be more for public relations, however, than to save fuel or reduce **pollution**. The electrical generators coupled to engines of these vehicles will produce only 12 volts of power. This is far less than the 42 volts needed to provide drive the wheels. Instead, the electricity generated by the gasoline-burning engine will only be used to power accessories such as video recorders, computers, on-board refrigerators, and the like. Having this electrical power available will probably actually increase fuel consumption rather than reduce it. For uncritical consumers, however, it provides a justification for continuing to drive huge, inefficient vehicles.

In 2002, President G. W. Bush announced he was abandoning the $1.5 billion government-subsidized project to develop high-mileage gasoline-fueled vehicles started with great fanfare eight years earlier by the Clinton/Gore administration. Instead, Bush was throwing his support behind a plan to develop hydrogen-based **fuel cells** to power the automobiles of the future. Fuel cells use a semi-permeable film or electrolyte that allows the passage of charged atoms, called ions, but is impermeable to electrons to generate an electrical current between an anode and cathode.

A fuel cell run on pure oxygen and **hydrogen** produces no waste products except drinkable water and radiant heat. **Fossil fuels** can be used as the source for the hydrogen, but some pollutants are released (most commonly **carbon dioxide**) in the process of hydrogen generation. Currently, the fuel cells available need to be quite large to provide enough energy for a vehicle. Fuel cell-powered buses and vans that have space for a large power system are currently being tested, but a practical, family vehicle appears to be years away.

While they agree that fuel cells offer a wonderful option for cars of the future, many environmentalists regard putting all our efforts into this one project to be misguided at best. It probably will be at least a decade before a fuel-cell vehicle is commercially available.

Hydrocarbons

Any compound composed of elemental **carbon** and **hydrogen**, hydrocarbons may also contain **chlorine**, oxygen, **nitrogen**, and other atoms. Hydrocarbons are classified according to the arrangement of carbon atoms and the types of chemical bonds. The major classes include *aromatic* or carbon ring

compounds, *alkanes* (also called aliphatic or paraffin) compounds with straight or branched chains and single bonds, and *alkenes* and *alkynes* with double and triple bonds, respectively. Most hydrocarbon fuels are a mixture of many compounds. **Gasoline**, for example, includes several hundred hydrocarbon compounds, including paraffins, olefins, and aromatic compounds, and consequently exhibits a host of possible environmental effects. All of the **fossil fuels**, including crude oils and **petroleum**, as well as many other compounds important to industries, are hydrocarbons. Hydrocarbons are environmentally important for several reasons. First, hydrocarbons give off **greenhouse gases**, especially **carbon dioxide**, when burned and are important contributers to **smog**. In addition, many aromatic hydrocarbons and hydrocarbons containing halogens are toxic or carcinogenic.

Hydrochlorofluorocarbons

The term hydrochlorofluorocarbon (HCFC) refers to halogenated **hydrocarbons** that contain **chlorine** and/or fluorine in place of some **hydrogen** atoms in the molecule. They are chemical cousins of the **chlorofluorocarbons** (CFCs), but differ from them in that they have less chlorine. A special subgroup of the HCFCs is the hydrofluorocarbons (HFCs), which contain no chlorine at all.

A total of 53 HCFCs and HFCs are possible.

The HCFCs and HFCs have become commercially and environmentally important since the 1980s. Their growing significance has resulted from increasing concerns about the damage being done to stratospheric **ozone** by CFCs.

Significant production of the CFCs began in the late 1930s. At first, they were used almost exclusively as refrigerants. Gradually other applications—especially as **propellants** and blowing agents—were developed. By 1970, the production of CFCs was growing by more than 10% per year, with a worldwide production of well over 662 million lb (300 million kg) of one family member alone, CFC-11.

Environmental studies began to show, however, that CFCs decompose in the upper **atmosphere**. Chlorine atoms produced in this reaction attack ozone molecules (O_3), converting them to normal oxygen (O_2). Since stratospheric ozone provides protection for humans against solar **ultraviolet radiation**, this finding was a source of great concern. By 1987, 31 nations had signed the Montreal Protocol, agreeing to cut back significantly on their production of CFCs.

The question became how nations were to find substitutes for the CFCs. The problem was especially severe in developing nations where CFCs are widely used in refrigeration and air-conditioning systems. Countries like China and India refused to take part in the CFC-reduction plan unless developed nations helped them switch over to an equally satisfactory substitute.

CHF_3	HFC-23
$CHCl_2CF_3$	HCFC-123
CH_2FCClF_2	HCFC-133b
CH_3CHClF	HCFC-151a

Scientists soon learned that HCFCs were a more benign alternative to the CFCs. They discovered that compounds with less chlorine than the amount present in traditional CFCs were less stable and often decomposed before they reached the **stratosphere**. By mid 1992, the United States **Environmental Protection Agency** (EPA) had selected 11 **chemicals** that they considered to be possible replacements for CFCs. Nine of those compounds are HFCs and two are HCFCs.

The HCFC-HFC solution is not totally satisfactory, however. Computer models have shown that nearly all of the proposed substitutes will have at least some slight effect on the ozone layer and the **greenhouse effect**. In fact, the British government considered banning one possible substitute for CFCs, HCFC-22, almost as soon as the compound was developed. In addition, one of the most promising candidates, HCFC-123, was found to be carcinogenic in rats.

Finally, the cost of replacing CFCs with HCFCs and HFCs is expected to be high. One consulting firm, Metroeconomica, has estimated that CFC substitutes may be six to 15 times as expensive as CFCs themselves. *See also* Aerosol; Air pollution; Air pollution control; Air quality; Carcinogen; Ozone layer depletion; Pollution; Pollution control

Hydrogen

The lightest of all chemical elements, hydrogen has a density about one-fourteenth that of air. It has a number of special chemical and physical properties. For example, hydrogen

has the second lowest boiling and freezing points of all elements. The **combustion** of hydrogen produces large quantities of heat, with water as the only waste product. From an environmental standpoint, this fact makes hydrogen a highly desirable fuel. Many scientists foresee the day when hydrogen will replace **fossil fuels** as our most important source of energy.

Hydrogeology

Sometimes called **groundwater hydrology** or geohydrology, this branch of hydrology is concerned with the relationship of subsurface water and geologic materials. Of primary interest is the saturated zone of subsurface water, called groundwater, which occurs in rock formations and in unconsolidated materials such as sands and gravels. Groundwater is studied in terms of its occurrence, amount, flow, and quality. Historically, much of the work in hydrogeology centered on finding sources of groundwater to supply water for drinking, **irrigation**, and municipal uses. More recently, groundwater contamination by pesticides, chemical fertilizers, toxic wastes, and **petroleum** and **chemical spills** have become new areas of concern for hydrogeologists.

Hydrologic cycle

The natural circulation of water on the earth is called the hydrologic cycle. Water cycles from bodies of water, via evaporation to the **atmosphere**, and eventually returns to the oceans as precipitation, **runoff** from streams and rivers, and **groundwater** flow. Water molecules are transformed from liquid to vapor and back to liquid within this cycle. On land, water evaporates from the **soil** or is taken up by plant roots and eventually transpired into the atmosphere through plant leaves; the sum of evaporation and **transpiration** is called **evapotranspiration**.

Water is recycled continuously. The molecules of water in a glass used to quench your thirst today, at some point in time may have dissolved minerals deep in the earth as groundwater flow, fallen as rain in a tropical typhoon, been transpired by a tropical plant, been temporarily stored in a mountain glacier, or quenched the thirst of people thousands of years ago.

The hydrologic cycle has no real beginning or end but is a circulation of water that is sustained by **solar energy** and influenced by the force of gravity. Because the supply of water on the earth is fixed, there is no net gain or loss of water over time. On an average annual basis, global evaporation must equal global precipitation. Likewise, for any body of land or water, changes in storage must equal the total inflow minus the total outflow of water. This is the hydrologic or water balance.

At any point in time, water on the earth is either in active circulation or in storage. Water is stored in icecaps, soil, groundwater, the oceans, and other bodies of water. Much of this water is only temporarily stored. The **residence time** of water storage in the atmosphere is several days and is only about 0.04% of the total freshwater on the earth. For rivers and streams, residence time is weeks; for lakes and reservoirs, several years; for groundwater, hundreds to thousands of years; for oceans, thousands of years; and for icecaps, tens of thousands of years. As the driving force of the hydrologic cycle, solar radiation provides the energy necessary to evaporate water from the earth's surface, almost three-quarters of which is covered by water. Nearly 86% of global precipitation originates from ocean evaporation. Energy consumed by the conversion of liquid water to vapor cools the temperature of the evaporating surface. This same energy, the latent heat of vaporization, is released when water vapor changes back to liquid. In this way, the hydrologic cycle globally redistributes heat energy as well as water.

Once in the atmosphere, water moves in response to weather circulation patterns and is transported often great distances from where it was evaporated. In this way, the hydrologic cycle governs the distribution of precipitation and hence, the availability of fresh water over the earth's surface. About 10% of atmospheric water falls as precipitation each day and is simultaneously replaced by evaporation. This 10% is unevenly distributed over the earth's surface and, to a large extent, determines the types of ecosystems that exist at any location on the earth and likewise governs much of the human activity that occurs on the land.

The earliest civilizations on the earth settled in close proximity to fresh water. Subsequently, and for centuries, humans have been striving to correct, or cope with, this uneven distribution of water. Historically, we have extracted stored water or developed new storages in areas of excess, or during periods of excess precipitation, so that water could be available where and when it is most needed.

Understanding processes of the hydrologic cycle can help us develop solutions to water problems. For example, we know that precipitation occurs unevenly over the earth's surface because of many complex factors that trigger precipitation. For precipitation to occur, moisture must be available and the atmosphere must become cooled to the **dew point**, the temperature at which air becomes saturated with water vapor. This cooling of the atmosphere occurs along storm fronts or in areas where moist air masses move into mountain ranges and are pushed up into colder air. However, atmospheric particles must be present for the moisture to con-

dense upon, and water droplets must coalesce until they are large enough to fall to the earth under the influence of gravity.

Recognizing the factors that cause precipitation has resulted in efforts to create conditions favorable for precipitation over land surfaces via cloud seeding. Limited success has been achieved by seeding clouds with particles, thus promoting the condensation-coalescence process. Precipitation has not always increased with cloud seeding and questions of whether cloud seeding limits precipitation in other downwind areas is of both economic and environmental concern.

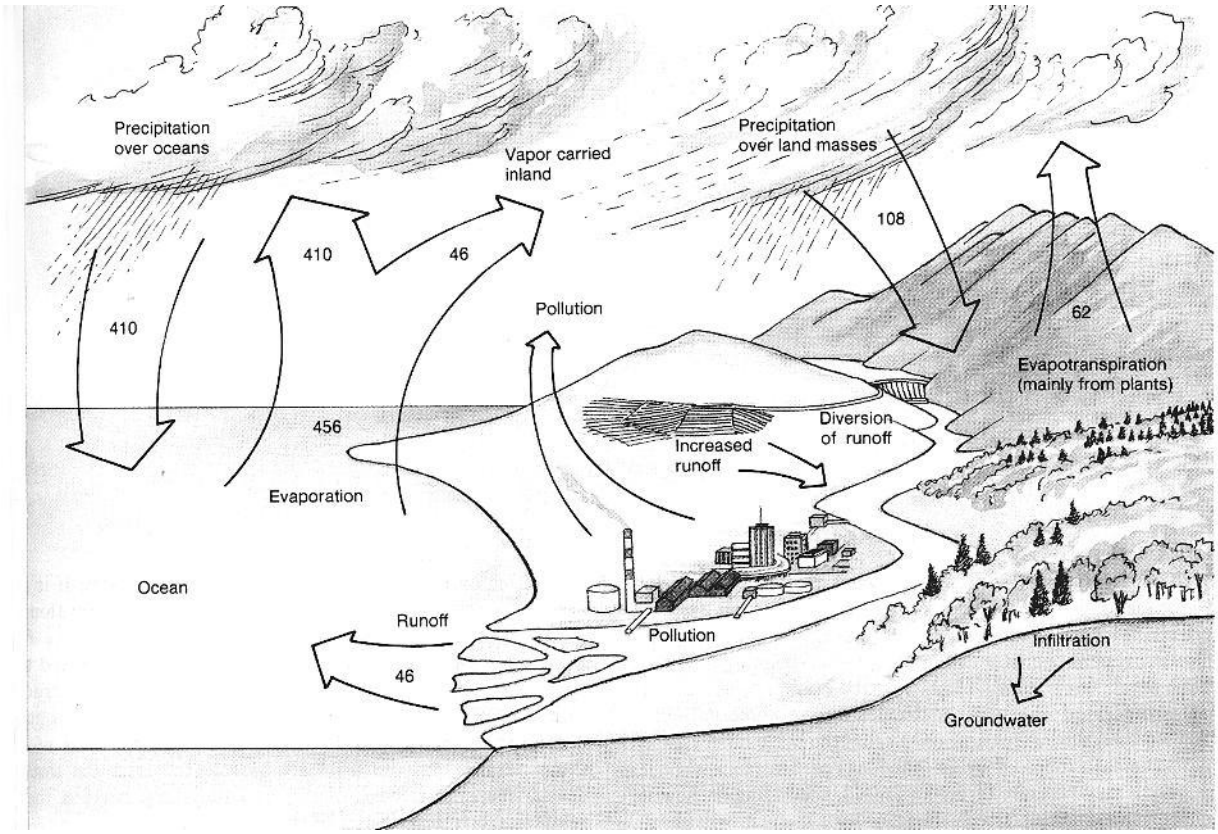
Parts of the world have abundant moisture in the atmosphere, but it occurs as fog because the mechanisms needed to transform this moisture into precipitation do not exist. In dry coastal areas, for example, some areas have no measurable precipitation for years, but fog is prevalent. By placing huge sheets of plastic mesh along coastal areas, fog is intercepted, condenses on the sheets, and provides sufficient drinking water to supply small villages.

Total rainfall alone does not necessarily indicate water abundance or **scarcity**. The magnitude of evapotranspiration compared to precipitation determines to some extent whether water is abundant or in short supply. On a continent basis, evapotranspiration represents from 56 to 80% of annual precipitation. For individual watersheds within continents, these%ages are more extreme and point to the importance of evapotranspiration in the hydrologic cycle.

Weather circulation patterns responsible for water shortages in some parts of the world are also responsible for excessive precipitation, floods, and related catastrophes in other parts of the world. Precipitation that falls on land, but that is not stored, evaporated or transpired, becomes excess water. This excess water eventually reaches groundwater, streams, lakes, or the ocean by surface and subsurface flow. If the soil surface is impervious or compacted, water flows over the land surface and reaches stream channels quickly. When surface flow exceeds a channel's capacity, flash **flooding** is the result. Excessive precipitation can saturate soils and cause flooding no matter what the pathway of flow. For example, in 1988 catastrophic flooding and mudslides in Thailand caused over 500 fatalities or missing persons, nearly 700 people were injured, 4,952 homes were lost, and 221 roads and 69 bridges were destroyed. A three-day rainfall of over nearly 40 in (1,000 mm) caused hillslopes to become saturated. The effects of heavy rainfall were exacerbated by the removal of natural forest cover and conversion to **rubber** plantations and agricultural crops.

Although floods and mudslides occur naturally, many of the pathways of water flow that contribute to such occurrences can be influenced by human activity. Any time vegetative cover is severely reduced and soil exposed to direct rainfall, surface water flow and soil **erosion** can degrade **watershed** systems and their aquatic ecosystems.

The implications of global warming or greenhouse effects on the hydrologic cycle raise several questions. The possible changes in frequency and occurrence of droughts and floods are of major concern, particularly given projections of **population growth**. Global warming can result in some areas becoming drier while others may experience higher precipitation. Globally, increased temperature will increase evaporation from oceans and ultimately result in more precipitation. The pattern of precipitation changes over the earth's surface, however, cannot be predicted at the present time.



The hydrologic cycle influences **nutrient** cycling of ecosystems, processes of soil erosion and transport of **sediment**, and the transport of pollutants. Water is an excellent liquid solvent; minerals, salts, and nutrients become dissolved and transported by water flow. The hydrologic cycle is an important driving mechanism of nutrient cycling. As a transporting agent, water moves minerals and nutrients to plant roots. As plants die and decay, water leaches out nutrients and carries them downstream. The physical action of rainfall on soil surfaces and the forces of running water can seriously erode soils and transport sediments downstream. Any minerals, nutrients, and pollutants within the soil are likewise transported by water flow into groundwater, streams, lakes, or estuaries.

Atmospheric moisture transports and deposits **atmospheric pollutants**, including those responsible for **acid rain**. Sulfur and **nitrogen oxides** are added to the atmosphere by the burning of **fossil fuels**. Being an excellent solvent, water in the atmosphere forms acidic compounds that become transported via the atmosphere and deposited great distances from their original site. Atmospheric pollutants and **acid** rain have damaged freshwater lakes in the Scandinavian countries and terrestrial vegetation in eastern Europe. In 1983, such **pollution** caused an estimated $1.2 billion loss of forests in the former West Germany alone. Once pollutants enter the atmosphere and become subject to the hydrologic cycle, problems of acid rain have little chance for resolution. However, programs that reduce atmospheric emissions in the first place provide some hope.

An improved understanding of the hydrologic cycle is needed to better manage **water resources** and our **environment**. Opportunities exist to improve our global environment, but better knowledge of human impacts on the hydrologic cycle is needed to avoid unwanted environmental effects. *See also* Estuary; Leaching

Hydrology

The science and study of water, including its physical and chemical properties and its occurrence on earth. Most commonly, hydrology encompasses the study of the amount, distribution, circulation, timing, and quality of water. It includes the study of rainfall, snow accumulation and melt, water movement over and through the **soil**, the flow of water in saturated, underground geologic materials (**groundwater**), the flow of water in channels (called streamflow), evaporation and **transpiration**, and the physical, chemical and biological characteristics of water. Solving problems concerned with water excesses, **flooding**, water shortages, and **water pollution** are in the domain of hydrologists. With increasing concern about water **pollution** and its effects on humans and on aquatic ecosystems, the practice of hydrology has expanded into the study and management of chemical and biological characteristics of water.

Hydroponics

Hydroponics is the practice of growing plants in water as opposed to **soil**. It comes from the Greek *hydro* ("water") and *ponos* ("labor"), implying "water working." The essential

macro- and micro- (trace) nutrients needed by the plants are supplied in the water.

Hydroponic methods have been used for more than 2,000 years, dating back to the Hanging Gardens of Babylon. More recently, it has been used by plant physiologists to discover which nutrients are essential for plant growth. Unlike soil, where **nutrient** levels are unknown and variable, precise amounts and kinds of minerals can be added to deionized water, and removed individually, to find out their role in plant growth and development. During World War II hydroponics was used to grow vegetable crops by U.S. troops stationed on some Pacific islands.

Today, hydroponics is becoming a more popular alternative to conventional agriculture in locations with low or inaccessible sources of water or where land available for farming is scarce. For example, islands and **desert** areas like the American Southwest and the Middle East are prime regions for hydroponics. Plants are typically grown in greenhouses to prevent water loss. Even in temperate areas where fresh water is readily available, hydroponics can be used to grow crops in greenhouses during the winter months.

Two methods are traditionally used in hydroponics. The original technique is the water method, where plants are supported from a wire mesh or similar framework so that the roots hang into troughs which receive continuous supplies of nutrients. A recent modification is a nutrient-film technique (NFT), also called the nutrient-flow method, where the trough is lined with plastic. Water flows continuously over the roots, decreasing the stagnant boundary layer surrounding each root, and thus enhances nutrient uptake. This provides a versatile, lightweight, and inexpensive system. In the second method, plants are supported in a growing medium such as sterile sand, gravel, crushed volcanic rock, vermiculite, perlite, sawdust, peatmoss, or rice hulls. The nutrient solution is supplied from overhead or underneath holding tanks either continuously or semi-continuously using a drip method. The nutrient solution is usually not reused.

On some Caribbean Islands like St. Croix, hydroponics is being used in conjunction with intensive fish farms (e.g., tilapia) which use recirculated water (a practice is more recently known as aquaponics). This is a "win-win" situation because the nitrogenous wastes, which are toxic to the fish, are passed through large greenhouses with hydroponically-grown plants like lettuce. The plants remove the nutrients and the water is returned to the fish tanks. There is a sensitive balance between stocking density of fish and lettuce production. Too high a ratio of lettuce plants to fish results in lower lettuce production due to nutrient limitation. Too low a ratio also results in low vegetable production, but this time as a result of the buildup of toxic **chemicals**. The optimum yield came from a ratio of 1.9 lettuce plants to 1 fish. One pound (0.45 kg) of feed per day was appropriate to feed 33 lb (15 kg) of tilapia fingerlings, which sustained 189 lettuce plants and produced nearly 3,300 heads of lettuce annually. When integrated systems (fish-hydroponic recirculating units) are compared to separate production systems, the results clearly favor the former. The combined costs and chemical requirements of the separate production systems was nearly two to three times greater than that of the recirculating system to produce the same amount of lettuce and fish. However, there are some drawbacks that must be considered—disease outbreaks in plants and/or fish; the need to critically maintain proper nutrient (especially trace element), plant, and fish levels; uncertainties in fish and market prices; and the need for highly-skilled labor. The integrated method can be adapted to grow other types of vegetables like strawberries, ornamental plants like roses, and other types of animals such as shellfish. Some teachers have even incorporated this technique into their classrooms to illustrate ecological as well as botanical and culture principles.

Some proponents of hydroponic gardening make fairly optimistic claims and state that a sophisticated unit is no more expensive than an equivalent parcel of farmed land. They also argue that hydroponic units (commonly called "hydroponicums") require less attention than terrestrial agriculture. Some examples of different types of "successful" hydroponicums are: a person in the desert area of southern California has used the NFT system for over 18 years and grows his plants void of substate in water contained in open cement troughs that cover 3 acres (7.5 ha); a hydroponicum in Orlando, Florida, utilizes the Japanese system of planting seedlings on styrofoam boards that float on the surface of a nutrient bath which is constantly aerated; an outfit in Queens, New York, uses the Israeli Ein-Gedi system which allows plant roots to hang free inside a tube which is sprayed regularly with a nutrient solution, yielding 150,000 lbs (68,000 kg) of tomatoes, 100,000 lb (45,500 kg) of cucumbers, and one million heads of lettuce per acre (0.4 ha) each year; and finally, a farmer in Blooming **Prairie**, Minnesota, uses the NFT system in a greenhouse to grow Bibb and leafy lettuce year-round so he can sell his produce to area hospitals, some supermarkets, and a few produce warehouses.

Most people involved in hydroponics agree that the main disadvantage is the high cost for labor, lighting, water, and energy. Root fungal infections can also be easily spread. Advantages include the ability to grow crops in **arid** regions or where land is at a premium; more controlled conditions, such as the ability to grow plants indoors, and thus minimize pests and weeds; greater planting densities; and constant supply of nutrients. Hydroponic gardening is becoming more popular for home gardeners. It may also be a viable option to growing crops in some developing countries. Overall, the future looks bright for hydroponics.

Hydrothermal vents

Hydrothermal vents are hot springs located on the ocean floor. The vents spew out water heated by magma, molten rock from below the earth's crust. Water temperatures of higher than 660°F. have been recorded at some vents.

Water flowing from vents contains minerals such as iron, **copper**, and zinc. The minerals fall like rain and settle on the ocean floor. Over time, the mineral deposits build up and form a chimney around the vent.

The first hydrothermal vents were discovered in 1977 by scientists aboard the submersible *Alvin*. The scientists found the vents near the **Galápagos Islands** in the eastern Pacific Ocean. Other vents were discovered in the Pacific, Atlantic, and Indian oceans.

In 2000, scientists discovered a field of hydrothermal vents in the Atlantic Ocean. The area called the "Lost City" contained 180-feet tall chimneys. These were the largest known chimneys.

Hydrothermal vents are located at ocean depths of 8,200 to 10,000 feet. The area near a hydrothermal vent is home to unique animals. They exist without sunlight and live in mineral-levels that would poison animals living on land. These unique animals include 10-foot-long tube worms, 1-foot-long clams, and shrimp.

Ice age

Ice age usually refers to the Pleistocene epoch, the most recent occurrence of continental **glaciation**. Beginning several million years ago in **Antarctica**, it is marked by at least four major advances and retreats (excluding Antarctica). Ice ages occur during times when more snow falls during the winter than is lost by melting, evaporation, and loss of ice chunks in water during the summer. Alternating glacial and interglacial stages are best explained by a combination of Earth's orbital cycles and changes in **carbon dioxide** levels. These cycles operate on time scales of tens of millennia. By contrast, global warming projections involve decades, a far more imminent concern for humankind.

Ice age refugia

The series of ice ages that occurred between 2.4 million and 10,000 years ago had a dramatic effect on the **climate** and the life forms in the tropics. During each glacial period the tropics became both cooler and drier, turning some areas of **tropical rain forest** into dry seasonal forest or **savanna**. For reasons associated with local **topography**, geography, and climate, some areas of forest escaped the dry periods, and acted as refuges (refugia) for forest biota. During subsequent interglacials, when humid conditions returned to the tropics, the forests expanded and were repopulated by plants and animals from the species-rich refugia.

Ice age refugia today correspond to present day areas of tropical forest that typically receive a high rainfall and often contain unusually large numbers of **species**, including a high proportion of **endemic species**. These species-rich refugia are surrounded by relatively species-poor areas of forest. Refugia are also centers of distribution for obligate forest species (such as the gorilla [*Gorilla gorilla*]) with a present day narrow and disjunct distribution best explained by invoking past episodes of **deforestation** and reforestation. The location and extent of the forest refugia have been mapped in both Africa and South America. In the African rain forests there are three main centers of species richness and endemism recognized for mammals, birds, reptiles, amphibians, butterflies, freshwater crabs, and flowering plants. These centers are in Upper Guinea, Cameroon, and Gabon, and the eastern rim of the Zaire basin. In the **Amazon Basin** more than 20 refugia have been identified for different groups of animals and plants in Peru, Columbia, Venezuela, and Brazil.

The precise effect of the ice ages on **biodiversity** in tropical rain forests is currently a matter of debate. Some have argued that the repeated fluctuations between humid and **arid** phases created opportunities for the rapid **evolution** of certain forest organisms. Others have argued the opposite — that the climatic fluctuations resulted in a net loss of species diversity through an increase in the **extinction** rate. It has also been suggested that refugia owe their species richness not to past climate changes but to other underlying causes such as a favorable local climate, or **soil**.

The discovery of centers of high biodiversity and endemism within the tropical **rain forest biome** has profound implications for **conservation biology**. A "refuge rationale" has been proposed by conservationists, whereby ice age refugia are given high priority for preservation, since this would save the largest number of species, (including many unnamed, threatened, and **endangered species**), from extinction.

Since refugia survived the past dry-climate phases, they have traditionally supplied the plants and animals for the restocking of the new-growth forests when wet conditions returned. Modern deforestation patterns, however, do not take into account forest history or biodiversity, and both forest refugia and more recent forests are being destroyed equally. For the first time in millions of years, future tropical

forests which survive the present mass deforestation episode could have no species-rich centers from which they can be restocked. *See also* Biotic community; Deciduous forest; Desertification; Ecosystem; Environment; Mass extinction

Impervious material

As used in **hydrology**, this term refers to rock and **soil** material that occurs at the earth's surface or within the subsurface which does not permit water to enter or move through them in any perceptible amounts. These materials normally have small-sized pores or have pores that have become clogged (sealed) which severely restrict water entry and movement. At the ground surface, rock outcrops, road surfaces, or soil surfaces that have been severely compacted would be considered impervious. These areas shed rainfall easily, causing overland flow or surface **runoff** which pick up and transport soil particles and cause excessive soil **erosion**. Soils or geologic strata beneath the earth's surface are considered impervious, or impermeable, if the size of the pores is small and/or if the pores are not connected.

Improvement cutting

Removal of crooked, forked, or diseased trees from a forest in which tree diameters are 5 in (13 cm) or larger. In forests where trees are smaller, the same process is called cleaning or weeding. Both have the objective of improving **species** composition, stem quality and/or growth rate of the forest. Straight, healthy, vigorous trees of the desired species are favored. By discriminating against certain tree species and eliminating trees with cavities or insect problems, improvement cuts can reduce the variety of habitats and thereby diminish **biodiversity**. An improvement cut is the initial step to prepare a neglected or unmanaged stand for future harvest. *See also* Clear-cutting; Forest management; Selection cutting

In situ mining

see **Bureau of Mines**

Inbreeding

Inbreeding occurs when closely related individuals mate with one another. Inbreeding may happen in a small population or due to other isolating factors; the consequence is that little new genetic information is added to the **gene pool**. Thus recessive, deleterious alleles become more plentiful and evident in the population. Manifestations of inbreeding are known as *inbreeding depression*. A general loss of fitness often results and may cause high infant **mortality**, and lower birth weights, **fecundity**, and longevity. Inbreeding depression is a major concern when attempting to protect small populations from **extinction**.

Incidental catch

see **Bycatch**

Incineration

As a method of **waste management**, incineration refers to the burning of waste. It helps reduce the volume of **landfill** material and can render toxic substances non-hazardous, provided certain strict guidelines are followed. There are two basic types of incineration: municipal and **hazardous waste** incineration.

Municipal waste incineration

The process of incineration involves the combination of organic compounds in solid wastes with oxygen at high temperature to convert them to ash and gaseous products. A municipal incinerator consists of a series of unit operations which include a loading area under slightly negative pressure to avoid the escape of odors, a refuse bin which is loaded by a grappling bucket, a charging hopper leading to an inclined feeder and a furnace of varying type—usually of a horizontal burning grate type—a **combustion** chamber equipped with a bottom ash and clinker **discharge**, followed by a gas flue system to an expansion chamber. If byproduct stream is to be produced either for heating or power generation purposes, then the downstream flue system includes heat exchanger tubing as well. After the heat has been exchanged, the **flue gas** proceeds to a series of gas cleanup

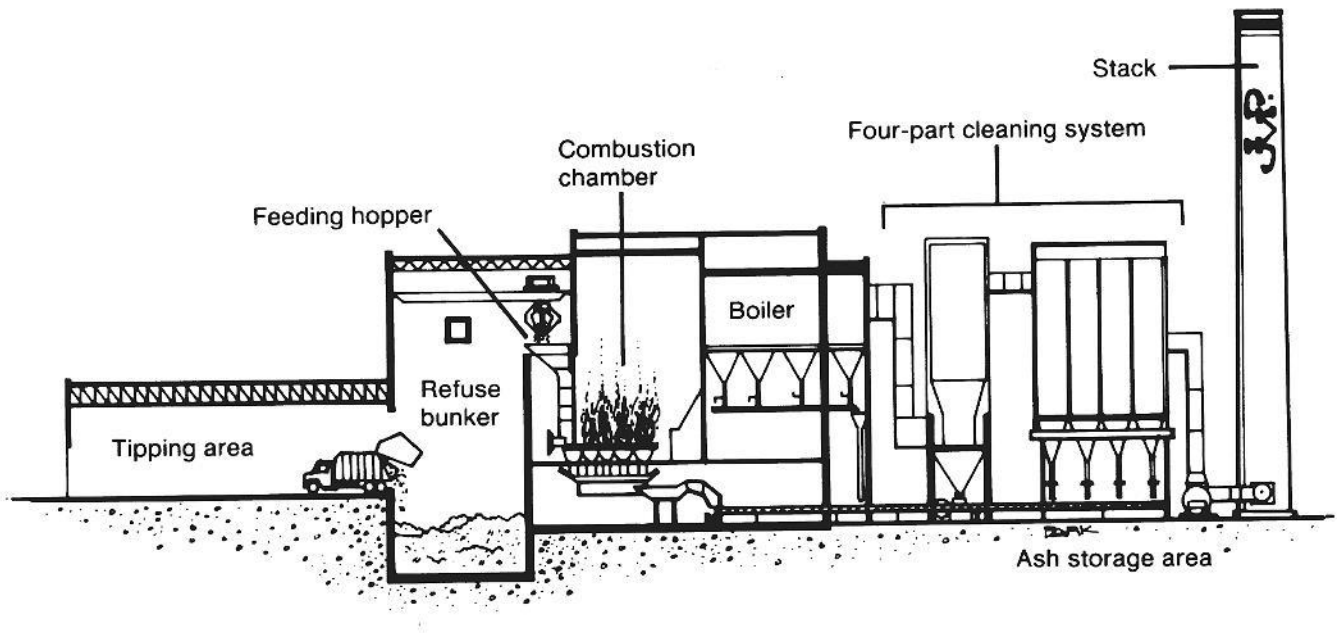

Diagram of a municipal incinerator. (McGraw-Hill Inc. Reproduced by permission.)

systems which neutralizes the **acid** gases (**sulfur dioxide** and hydrochloric acid, the latter resulting from burning chlorinated plastic products), followed by gas **scrubbers** and then solid/gas separation systems such as baghouses before dischargement to **tall stacks**. The stack system contains a variety of sensing and control devices to enable the furnace to operate at maximum efficiency consistent with minimal **particulate** emissions. A continuous log of monitoring systems is also required for compliance with county and state environmental quality regulations.

There are several products from a municipal incinerator system: items which are removed before combustion such as large metal pieces; grate or bottom ash (which is usually water-sprayed after removal from the furnace for safe storage); fly (or top ash) which is removed from the flue system generally mixed with products from the acid neutralization process; and finally the flue gases which are expelled to the **environment**. If the system is operating optimally, the flue gases will meet **emission** requirements, and the **heavy metals** from the wastes will be concentrated in the **fly ash**. (Typically these heavy metals, which originate from volatile metallic constituents, are **lead** and arsenic.) The fly ash typically is then stored in a suitable landfill to avoid future problems of **leaching** of heavy metals. Some municipal systems blend the bottom ash with the top ash in the plant in order to reduce the level of heavy metals by dilution. This practice is undesirable from an ultimate environmental viewpoint.

There are many advantages and disadvantages to municipal waste incineration. Some of the advantages are as follows: 1) The waste volume is reduced to a small fraction of the original. 2) Reduction is rapid and does not require semi-infinite residence times in a landfill. 3) For a large metropolitan area, waste can be incinerated on site, minimizing **transportation** costs. 4) The ash residue is generally sterile, although it may require special disposal methods. 5) By use of gas clean-up equipment, discharges of flue gases to the environment can meet stringent requirements and be readily monitored. 6) Incinerators are much more compact than landfills and can have minimal odor and vermin problems if properly designed. 7) Some of the costs of operation can be reduced by heat-recovery techniques such as the sale of steam to municipalities or electrical energy generation.

There are disadvantages to municipal waste incineration as well. For example: 1) Generally the capital cost is

high and is escalating as **emission standards** change. 2) Permitting requirements are becoming increasingly more difficult to obtain. 3) Supplemental fuel may be required to burn municipal wastes, especially if **yard waste** is not removed prior to collection. 4) Certain items such as mercury-containing batteries can produce emissions of **mercury** which the gas cleanup system may not be designed to remove. 5) Continuous skilled operation and close maintenance of process control is required, especially since stack monitoring equipment reports any failure of the equipment which could result in mandated shut down. 6) Certain materials are not burnable and must be removed at the source. 7) Traffic to and from the incinerator can be a problem unless timing and routing are carefully managed. 8) The incinerator, like a landfill, also has a limited life, although its lifetime can be increased by capital expenditures. 9) Incinerators also require landfills for the ash. The ash usually contains heavy metals and must be placed in a specially-designed landfill to avoid leaching.

Hazardous waste incineration

For the incineration of hazardous waste, a greater degree of control, higher temperatures, and a more rigorous monitoring system are required. An incinerator burning hazardous waste must be designed, constructed, and maintained to meet **Resource Conservation and Recovery Act** (RCRA) standards. An incinerator burning hazardous waste must achieve a destruction and removal efficiency of at least 99.99 percent for each principal organic hazardous constituent. For certain listed constituents such as polychlorinated biphenyl (PCB), mass air emissions from an incinerator are required to be greater than 99.9999%. The Toxic Substances Control Act requires certain standards for the incineration of PCBs. For example, the flow of PCB to the incinerator must stop automatically whenever the combustion temperature drops below the specified value; there must be continuous monitoring of the stack for a list of emissions; scrubbers must be used for hydrochloric acid control; among others.

Recently medical wastes have been treated by steam sterilization, followed by incineration with treatment of the flue gases with activated **carbon** for maximum **absorption** of organic constituents. The latter system is being installed at the Mayo Clinic in Rochester, Minnesota, as a model medical disposal system. *See also* Fugitive emissions; Solid waste incineration; Solid waste volume reduction; Stack emissions

Indicator organism

Indicator organisms, sometimes called bioindicators, are plant or animal **species** known to be either particularly tolerant or particularly sensitive to **pollution**. The health of an organism can often be associated with a specific type or intensity of pollution, and its presence can then be used to indicate polluted conditions relative to unimpacted conditions.

Tubificid worms are an example of organisms that can indicate pollution. Tubificid worms live in the bottom sediments of streams and lakes, and they are highly tolerant of sewage. In a river polluted by **wastewater discharge** from a **sewage treatment** plant, it is common to see a large increase in the numbers of tubificid worms in stream sediments immediately downstream. Upstream of the discharge, the numbers of tubificid worms are often much lower or almost absent, reflecting cleaner conditions. The number of tubificid worms also decreases downstream, as the discharge is diluted.

Pollution-intolerant organisms can also be used to indicate polluted conditions. The larvae of mayflies live in stream sediments and are known to be particularly sensitive to pollution. In a river receiving wastewater discharge, mayflies will show the opposite pattern of tubificid worms. The mayfly larvae are normally present in large numbers above the discharge point; they decrease or disappear at the discharge point and reappear further downstream as the effects of the discharge are diluted.

Similar examples of indicator organisms can be found among plants, fish, and other biological groups. Giant reedgrass (*Phragmites australis*) is a common marsh plant that is typically indicative of disturbed conditions in **wetlands**. Among fish, disturbed conditions may be indicated by the disappearance of sensitive species like trout which require clear, cold waters to thrive.

The usefulness of indicator organisms is limited. While their presence or absence provides a reliable general picture of polluted conditions, they are often little help in

identifying the exact sources of pollution. In the sediments of New York Harbor, for example, pollution-tolerant insect larvae are overwhelmingly dominant. However, it is impossible to attribute the large larval populations to just one of the sources of pollution there, which include ship traffic, sewage and industrial discharge, and **storm runoff**.

The U.S. **Environmental Protection Agency** (EPA) is working diligently to find reliable predictors of aquatic **ecosystem health** using indicator species. Recently, the EPA has developed standards for the usefulness of species as ecological indicator organisms. A potential indicator species for use in evaluating **watershed** health must successfully pass four phases of evaluation. First, a potential indicator organism should provide information that is relevant to societal concerns about the **environment**, not simply academically interesting information. Second, use of a potential indicator organism should be feasible. Logistics, sampling costs, and timeframe for information gathering are legitimate considerations in deciding whether an organism is a potential indicator species or not. Thirdly, enough must be known about a potential species before it may be effectively used as an indicator organism. Sufficient knowledge regardin! g the natural variations to environmental flux should exist before incorporating a species as a true watershed indicator species. Lastly, the EPA has set a fourth criterion for evaluation of indicator species. A useful indicator should provide information that is easily interpreted by policy makers and the public, in addition to scientists.

Additionally, in an effort to make indicator species information more reliable, the creation of indicator species indices are being investigated. An index is a formula or ratio of one amount to another that is used to measure relative change. The major advantage of developing an indicator organism index that is somewhat universal to all aquatic environments is that it can be tested using **statistics**. Using mathematical statistical methods, it may be determined whether a significant change in an index value has occurred. Furthermore, statistical methods allow for a certain level of confidence that the measured values repres! ent what is actually happening in **nature**. For example, a study was conducted to evaluate the utility of diatoms (a kind of microscopic aquatic algae) as an index of aquatic system health. Diatoms meet all four criteria mentioned above, and various species are found in both fresh and salt water. An index was created that was calculated using various measurable characteristics of diatoms that could then be evaluated statistically over time and among varying sites. It was determined that the diatom index was sensitive enough to reliably reflect three categories of the health of an aquatic **ecosystem**. The diatom index showed that values obtained from areas impacted by human activities had greater variability over time than diatom indices obtained from less disturbed locations. Many such indices are being developed using different species, and multiple species in an effort to create reliable information from indicator organisms. As more is learned about the physiology and life history of indicator organisms and their individual responses to different types of pollution, it may be possible to draw more specific conclusions. *See also* Algal bloom; Nitrogen cycle; Water pollution

Indigenous peoples

Cultural or ethnic groups living in an area where their culture developed or where their people have existed for many generations. Most of the world's indigenous peoples live in remote forests, mountains, deserts, or arctic **tundra**, where modern technology, trade, and cultural influence are slow to penetrate. Many had much larger territories historically but have retreated to, or been forced into, small, remote areas by the advance of more powerful groups. Indigenous groups, also sometimes known as native or tribal peoples, are usually recognized in comparison to a country's dominant cultural group. In the United States the dominant, non-indigenous cultural groups speak English, has historic roots in Europe, and maintain strong economic, technological, and communication ties with Europe, Asia, and other parts of the world. Indigenous groups in the United States, on the other hand, include scores of groups, from the southern Seminole and Cherokee to the Inuit and Yupik peoples of the Arctic coast. These groups speak hundreds of different languages or dialects, some of which have been on this continent for thousands of years. Their traditional economies were based mainly on small-scale subsistence gathering, **hunting**, fishing, and farming. Many indigenous peoples around the world continue to engage in these ancient economic practices.

It is often difficult to distinguish who is and who is not indigenous. European-Americans and Asian-Americans are usually not considered indigenous even if they have been here for many generations. This is because their cultural roots connect to other regions. On the other hand, a German residing in Germany is also not usually spoken of as indigenous, even though by any strict definition she or he *is* indigenous. This is because the term is customarily reserved to denote economic or political minorities—groups that are relatively powerless within the countries where they live.

Historically, indigenous peoples have suffered great losses in both population and territory to the spread of larger, more technologically advanced groups, especially (but not only) Europeans. Hundreds of indigenous cultures have disappeared entirely just in the past century. In recent decades, however, indigenous groups have begun to receive greater international recognition, and they have begun to learn effective means to defend their lands and interests—including attracting international media attention and suing their own governments in court. The main reason for this increased attention and success may be that scientists and economic development organizations have recently become interested in biological diversity and in the loss of world rain forests. The survival of indigenous peoples, of the world's forests, and of the world's gene pools are now understood to be deeply interdependent. Indigenous peoples, who know and depend on some of the world's most endangered and biologically diverse ecosystems, are increasingly looked on as a unique source of information, and their subsistence economies are beginning to look like admirable alternatives to large-scale **logging**, mining, and conversion of jungles to monocrop agriculture.

There are probably between 4,000 and 5,000 different indigenous groups in the world; they can be found on every continent (except **Antarctica**) and in nearly every country. The total population of indigenous peoples amounts to between 200 million and 600 million (depending upon how groups are identified and their populations counted) out of a world population just over 6.2 billion. Some groups number in the millions; others comprise only a few dozen people. Despite their world-wide distribution, indigenous groups are especially concentrated in a number of "cultural diversity hot spots," including Indonesia, India, Papua New Guinea, **Australia**, Mexico, Brazil, Zaire, Cameroon, and Nigeria. Each of these countries has scores, or even hundreds, of different language groups. Neighboring valleys in Papua New Guinea often contain distinct cultural groups with unrelated languages and religions. These regions are also recognized for their unusual biological diversity. Both indigenous cultures and **rare species** survive best in areas where modern technology does not easily penetrate. Advanced technological economies involved in international trade consume tremendous amounts of land, wood, water, and minerals. Indigenous groups tend to rely on intact ecosystems and on a tremendous variety of plant and animal **species**. Because their numbers are relatively small and their technology simple, they usually do little long-lasting damage to their **environment** despite their dependence on the resources around them. The remote areas where indigenous peoples and their natural environment survive, however, are also the richest remaining reserves of **natural resources** in most countries. Frequently state governments claim all timber, mineral, water, and land rights in areas traditionally occupied by tribal groups. In Indonesia, Malaysia, Burma (Myanmar), China, Brazil, Zaire, Cameroon, and many other important cultural diversity regions, timber and mining concessions are frequently sold to large or international companies that can quickly and efficiently destroy an ecological area and its people. Usually native peoples, because they lack political and economic clout, have no recourse to losing their homes. Generally they are relocated, attempts are made to integrate them into mainstream culture, and they join laboring classes in the general economy.

Indigenous rights have begun to strengthen in recent years. As long as international media attention continues to give them the attention they need—especially in the form of international economic and political pressure on state governments—and as long as indigenous leaders are able to continue developing their own defense strategies and legal tactics, the survival rate of indigenous peoples and their environments may improve significantly.

Indonesian forest fires

For several months in 1997 and 1998, a thick pall of **smoke** covered much of Southeast Asia. Thousands of forest fires burning simultaneously on the Indonesian islands of Kalimantan (Borneo) and Sumatra, are thought to have destroyed about 8,000 mi^2 (20,000 km^2) of primary forest, or an area about the size of New Jersey. The smoke generated by these fires spread over eight countries and 75 million people, covering an area larger than Europe. Hazy skies and the smell of burning forests could be detected in Hong Kong, nearly 2,000 mi (3,200 km) away. The **air quality** in Singapore and the city of Kuala Lumpur, Malaysia, just across the Strait of Malacca from Indonesia, was worse than any industrial region in the world. In towns such as Palembang, Sumatra, and Banjarmasin, Kalimantan, in the heart of the fires, the **air pollution index** frequently passed 800, twice the level classified in the United States as an air quality emergency, hazardous to human health. Automobiles had to drive with their headlights on, even at noon. People

groped along smoke-darkened streets unable to see or breathe normally.

At least 20 million people in Indonesia and Malaysia were treated for illnesses such as **bronchitis**, eye irritation, **asthma**, **emphysema**, and cardiovascular diseases. It's thought that three times that many who couldn't afford medical care went uncounted. The number of extra deaths from this months-long episode is unknown, but it seems likely to have been hundreds of thousands, mostly elderly or very young children. Unable to see through the thick **haze**, several boats collided in the busy Straits of Malacca, and a plane crashed on Sumatra, killing 234 passengers. Cancelled airline flights, aborted tourist plans, lost workdays, medical bills, and ruined crops are estimated to have cost countries in the afflicted area several billion dollars. **Wildlife** suffered as well. In addition to the loss of **habitat** destroyed by fires, breathing the noxious smoke was as hard on wild **species** as it was on people. At the Pangkalanbuun Conservation Reserve, weak and disoriented orangutans were found suffering from **respiratory diseases** much like those of humans.

Geographical isolation on the 16,000 islands of the Indonesian archipelago has allowed **evolution** of the world's richest collection of **biodiversity**. Indonesia has the second largest expanse of tropical forest and the highest number of **endemic species** anywhere. This makes destruction of Indonesian plants, animals, and their habitat of special concern. The dry season in tropical Southeast Asia has probably always been a time of burning vegetation and smoky skies. Farmers practicing traditional **slash and burn agriculture** start fires each year to prepare for the next growing season. Because they generally burn only a hectare or two at a time, however, these shifting cultivators often help preserve plant and animal species by opening up space for early successional forest stages. Globalization and the advent of large, commercial plantations, however, have changed agricultural dynamics. There is now economic incentive for clearing huge tracts of forestland to plant oil palms, export foods such as pineapples and sugar cane, and fast-growing eucalyptus trees. Fire is viewed as the only practical way remove **biomass** and convert wild forest to into domesticated land. While it can cost the equivalent of $200 to clear a hectare of forest with chainsaws and bulldozers, dropping a lighted match into dry underbrush is essentially free.

In 1997 to 1998, the Indonesian forest was unusually dry. A powerful El Niño/Southern Oscillation weather pattern caused the most severe droughts in 50 years. Forests that ordinarily stay green and moist even during the rainless season became tinder dry. Lightning strikes are thought to have started many forest fires, but many people took advantage of the **drought** for their own purposes. Although the government blamed traditional farmers for setting most of the fires, environmental groups claimed that the biggest fires were caused by large agribusiness conglomerates with close ties to the government and military. Some of these fires were set to cover up evidence of illegal **logging** operations. Others were started to make way for huge oil-palm plantations and fast-growing pulpwood trees,

Neil Byron of the Center for International Forestry Research was quoted as saying that "fire crews would go into an area and put out the fire, then come back four days later and find it burning again, and a guy standing there with a petrol can." According to the World Wide Fund for Nature, 37 plantations in Sumatra and Kalimantan were responsible for a vast majority of the forest burned on those islands. The plantation owners were politically connected to the ruling elite, however, and none of them was ever punished for violation of **national forest** protection laws. Indonesia has some of the strongest land-use management laws of any country in the world, but these laws are rarely enforced. In theory, more than 80% of its land is in some form of protected status, either set aside as national parks or classified as selective logging reserves where only a few trees per hectare can be cut. The government claims to have an ambitious reforestation program that replants nearly 1.6 million acres (1 million hectares) of harvested forest annually, but when four times that amount is burned in a single year, there's not much to be done but turn it over to plantation owners for use as agricultural land.

Aquatic life, also, is damaged by these forest fires. Indonesia, Malaysia, and the Philippines have the richest **coral reef** complexes in the world. More than 150 species of coral live in this area, compared with only about 30 species in the Caribbean. The clear water and fantastic biodiversity of Indonesia's reefs have made it an ultimate destination for scuba divers and snorkelers from around the world. Unfortunately, **soil** eroded from burned forests clouds coastal waters and smothers reefs.

Perhaps one of the worst effects of large tropical forest fires is that they may tend to be self-reinforcing. Moist tropical forests store huge amounts of **carbon** in their standing biomass. When this carbon is converted into CO_2 by fire and released to the **atmosphere**, it acts as a greenhouse gas to trap heat and cause global warming. All the effects of human-caused global **climate** change are still unknown, but we stronger climatic events such as severe droughts may make further fires even more likely. Alarmed by the magnitude of the Southeast Asia fires and the potential they represent for biodiversity losses and global climate change, world leaders have proposed plans for international intervention to prevent A recurrence. Fears about imposing on national sovereignty, however, have made it difficult to come up with a plan for how to cope with this growing threat.

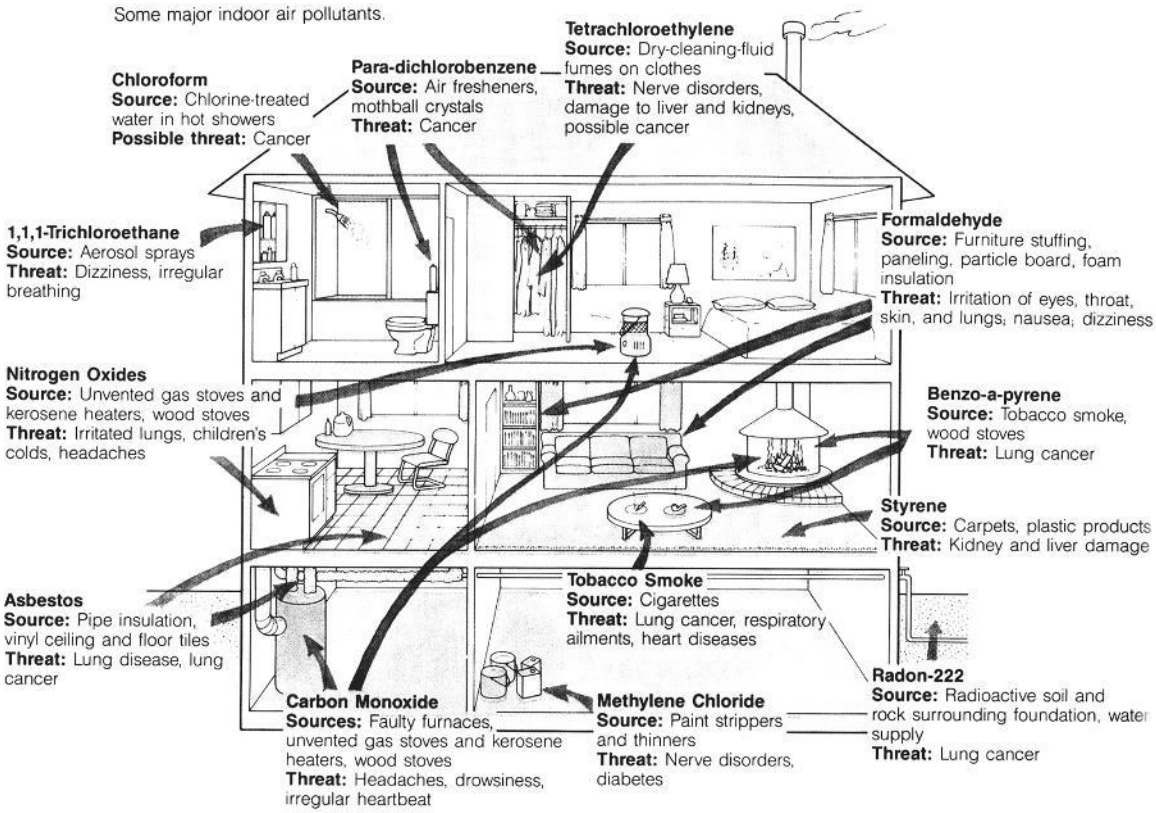
Indoor air quality

An assessment of **air quality** in buildings and homes based on physical and chemical monitoring of contaminants, physiological measurements, and/or psychosocial perceptions. Factors contributing to the quality of indoor air include lighting, ergonomics, thermal comfort, **tobacco smoke**, noise, ventilation, and psychosocial or work-organizational factors such as employee stress and satisfaction. "Sick building syndrome" (SBS) and "building-related illness" (BRI) are responses to indoor **air pollution** commonly described by office workers. Most symptoms are nonspecific; they progressively worsen during the week, occur more frequently in the afternoon, and disappear on the weekend.

Poor indoor air quality (IAQ) in industrial settings such as factories, **coal** mines, and foundries has long been recognized as a health risk to workers and has been regulated by the U.S. **Occupational Safety and Health Administration** (OSHA). The contaminant levels in industrial settings can be hundreds or thousands of times higher than the levels found in homes and offices. Nonetheless, indoor air quality in homes and offices has become an environmental priority in many countries, and federal IAQ legislation has been introduced in the U.S. Congress for the past several years. However, none has yet passed, and currently the U.S. **Environmental Protection Agency** (EPA) has no enforcement authority in this area.



Importance of IAQ

The prominence of IAQ issues has risen in part due to well-publicized incidents involving outbreaks of Legionnaires' disease, Pontiac fever, **sick building syndrome**, **multiple chemical sensitivity**, and **asbestos** mitigation in public buildings such as schools. Legionnaire's disease, for example, caused twenty-nine deaths in 1976 in a Philadelphia hotel due to infestation of the building's air conditioning system by a bacterium called *Legionella pneumophila*. This microbe affects the gastrointestinal tract, kidneys, and central nervous system. It also causes the non-fatal Pontiac fever.

IAQ is important to the general public for several reasons. First, individuals typically spend the vast majority of their time—80–90%—indoors. Second, an emphasis on **energy conservation** measures, such as reducing air exchange rates in ventilation systems and using more energy efficient but synthetic materials, has increased levels of air contaminants in offices and homes. New "tight" buildings have few cracks and openings so minimal fresh air enters such buildings. Low ventilation and exchange rates can increase indoor levels of **carbon monoxide**, **nitrogen oxides**, **ozone**, volatile organic compounds, **bioaerosols**, and pesticides and maintain high levels of second-hand tobacco smoke generated inside the building. Thus, many contaminants are found indoors at levels that greatly exceed outdoor levels. Third, an increasing number of synthetic chemicals—found in building materials, furnishing, cleaning and hygiene products—are used indoors. Fourth, studies show that exposure to indoor contaminants such as **radon**, asbestos, and tobacco smoke pose significant health risks. Fifth, poor IAQ is thought to adversely affect children's development and lower productivity in the adult population. Demands for indoor air quality investigations of "sick" and problem buildings have increased rapidly in recent years, and a large fraction of buildings are known or suspected to have IAQ problems.

Indoor contaminants

Indoor air contains many contaminants at varying but generally low concentration levels. Common contaminants include radon and radon progeny from the entry of **soil** gas and **groundwater** and from concrete and other mineral-based building materials; tobacco smoke from cigarette and pipe smoking; formaldehyde from polyurethane foam insulation and building materials; volatile organic compounds (VOCs) emitted from binders and resins in carpets, furniture, or building materials, as well as VOCs used in **dry cleaning** processes and as **propellants** and constituents of personal use and cleaning products, like hair sprays and polishes; pesticides and insecticides; **carbon** monoxide, **nitrogen** oxides, and other **combustion** productions from gas stoves, appliances, and vehicles; asbestos from high temperature insulation; and biological contaminants including viruses, bacteria, molds, pollen, dust mites, and indoor and outdoor biota. Many or most of these contaminants are present at low levels in all indoor environments.

Some major indoor air pollutants. (Wadsworth Inc. Reproduced by permission.)

The quality of indoor air can change rapidly in time and from room to room. There are many diverse sources that emit various physical and chemical forms of contaminants. Some releases are slow and continuous, such as outgassing associated with building and furniture materials, while others are nearly instantaneous, like the use of cleaners and aerosols. Many building surfaces demonstrate significant interactions with contaminants in the form of sorption-desorption processes. Building-specific variation in air exchange rates, mixing, **filtration**, building and furniture surfaces, and other factors alter dispersion mechanisms and contaminant lifetimes. Most buildings employ **filters** that can remove particles and aerosols. Filtration systems do not effectively remove very small particles and have no effect on gases, vapors, and odors. Ventilation and air exchange units designed into the heating and cooling systems of buildings are designed to diminish levels of these contaminants by dilution. In most buildings, however, ventilation systems are turned off at night after working hours, leading to an increase in contaminants through the night. Though operation and maintenance issues are estimated to cause the bulk of indoor air quality problems, deficiencies in the design of the heating, ventilating and air conditioning (HVAC) system can cause problems as well. For example, locating a building's fresh air intake near a truck loading dock will bring diesel fumes and other noxious contaminants into the building.

Health impacts

Exposures to indoor contaminants can cause a variety of health problems. Depending on the pollutant and exposure, health problems related to indoor air quality may include non-malignant respiratory effects, including mucous membrane irritation, allergic reactions, and **asthma**; cardiovascular effects; infectious diseases such as Legionnaires' disease; immunologic diseases such as hypersensitivity pneumonitis; skin irritations; malignancies; neuropsychiatric effects; and other non-specific **systemic** effects such as lethargy, headache, and nausea. In addition indoor air contaminants such as radon, formaldehyde, asbestos, and other **chemicals** are suspected or known carcinogens. There is also growing concern over the possible effects of low level exposures on suppressing reproductive and growth capabilities and impacting the immune, endocrine, and nervous systems.

Solving IAQ problems

Acute indoor air quality problems can be greatly eliminated by identifying, evaluating, and controlling the sources of contaminants. IAQ control strategies include the use of higher ventilation and air exchange rates, the use of lower **emission** and more benign constituents in building and consumer products (including product use restriction regulations), air cleaning and filtering, and improved building practices in new construction. Radon may be reduced by inexpensive subslab ventilation systems. New buildings could implement a day of "bake-out," which heats the building to temperatures over 90°F (32°C) to drive out volatile organic compounds. Filters to remove ozone, organic compounds, and sulfur gases may be used to condition incoming and recirculated air. Copy machines and other emission sources should have special ventilation systems. Building designers, operators, contractors, maintenance personnel, and occupants are recognizing that healthy buildings result from combined and continued efforts to control emission sources, provide adequate ventilation and air cleaning, and good maintenance of building systems. Efforts toward this direction will greatly enhance indoor air quality.

Industrial waste treatment

Many different types of solid, liquid, and gaseous wastes are discharged by industries. Most industrial waste is recycled, treated and discharged, or placed in a **landfill**. There is no one means of managing industrial wastes because the nature of the wastes varies widely from one industry to another. One company might generate a waste that can be treated readily and discharged to the **environment** (direct **discharge**) or to a sewer in which case final treatment might be accomplished at a publicly owned treatment works (POTW). Treatment at the company before discharge to a sewer is referred to as pretreatment. Another company might generate a waste which is regarded as hazardous and therefore requires special management procedures related to storage, **transportation** and final disposal.

The pertinent legislation governing to what extent wastewaters need to be treated before discharge is the 1972 **Clean Water Act** (CWA). Major amendments to the CWA were passed in 1977 and 1987. The **Environmental Protection Agency** (EPA) was also charged with the responsibility of regulating the priority pollutants under the CWA. The CWA specifies that toxic and nonconventional pollutants are to be treated with the Best Available Technology (BAT). Gaseous pollutants are regulated under the **Clean Air Act** (CAA), promulgated in 1970 and amended in 1977 and 1990. An important part of the CAA consists of measures to attain and maintain National Ambient Air Quality Standards (NAAQS). Hazardous air pollutant (HAP) emissions are to be controlled through Maximum Achievable Control Technology (MACT) which can include process changes, material substitutions and/or **air pollution control** equipment. The "cradle to grave" management of hazardous wastes is to be performed in accordance with the **Resource Conservation and Recovery Act** (RCRA) of 1976 and the Hazardous and **Solid Waste** Amendments (HSWA) of 1984.

In 1990, the United States, through the **Pollution Prevention Act**, adopted a program designed to reduce the volume and toxicity of waste discharges. **Pollution** prevention (P2) strategies might involve changing process equipment or chemistry, developing new processes, eliminating products, minimizing wastes, **recycling** water or **chemicals**, trading wastes with another company, etc. In 1991, the EPA instituted the 33/50 program which was to result in an overall 33% reduction of 17 high priority pollutants by 1992 and a 50% reduction of the pollutants by 1995. Both goals were surpassed. Not only has this program been successful, but it sets an important precedence because the participating companies volunteered. Additionally, P2 efforts have led industries to rigorously think through product life cycles. A Life Cycle Analysis (LCA) starts with consideration for acquiring raw materials, moves through the stages related to processing, assembly, service and **reuse**, and ends with retirement/disposal. The LCA therefore reveals to industry the costs and problems versus the benefits for every stage in the life of a product.

In designing a **waste management** program for an industry, one must think first in terms of P2 opportunities, identify and characterize the various solid, liquid and gaseous waste streams, consider relevant legislation, and then design an appropriate waste management system. Treatment systems that rely on physical (e.g., settling, floatation, screening, **sorption**, membrane technologies, air stripping) and chemical (e.g., coagulation, precipitation, chemical oxidation and reduction, **pH** adjustment) operations are referred to as physicochemical, whereas systems in which **microbes** are cultured to metabolize waste constituents are known as biologi-

cal processes (e.g., **activated sludge**, trickling **filters**, biotowers, aerated lagoons, **anaerobic digestion**, **aerobic** digestion, **composting**). Oftentimes, both physicochemical and biological systems are used to treat solid and liquid waste streams. Biological systems might be used to treat certain gas streams, but most waste gas streams are treated physicochemically (e.g., cyclones, electrostatic precipitators, **scrubbers**, bag filters, thermal methods). Solids and the sludges or residuals that result from treating the liquid and gaseous waste streams are also treated by means of physical, chemical, and biological methods.

In many cases, the systems used to treat wastes from domestic sources are also used to treat industrial wastes. For example, municipal wastewaters often consist of both domestic and industrial waste. The local POTW therefore may be treating both types of wastes. To avoid potential problems caused by the input of industrial wastes, municipalities commonly have pretreatment programs which require that industrial wastes discharged to the sewer meet certain standards. The standards generally include limits for various toxic agents such as metals, organic matter measured in terms of **biochemical oxygen demand** (bod) or **chemical oxygen demand**, nutrients such as **nitrogen** and **phosphorus**, pH and other contaminants that are recognized as having the potential to impact on the performance of the POTW. At the other end of the spectrum, there are wastes that need to be segregated and managed separately in special systems. For example, an industry might generate a **hazardous waste** that needs to be placed in barrels and transported to an EPA approved treatment, storage or disposal facility (TSDF).

Thus, it is not possible to simply use one train of treatment operations for all industrial waste streams, but an effective, generic strategy has been developed in recent years for considering the waste management options available to an industry. The basis for the strategy is to look for P2 opportunities and to consider the life cycle of a product. An awareness of **waste stream** characteristics and the potential benefits of stream segregation is then melded with the knowledge of regulatory compliance issues and treatment system capabilities/performance to minimize environmental risks and costs.

Inertia

see **Resistance (inertia)**

Infiltration

In **hydrology**, infiltration refers to the maximum rate at which a **soil** can absorb precipitation. This is based on the initial moisture content of the soil or on the portion of precipitation that enters the soil. In soil science, the term refers to the process by which water enters the soil, generally by downward flow through all or part of the soil surface. The rate of entry relative to the amount of water being supplied by precipitation or other sources determines how much water enters the root zone and how much runs off the surface. *See also* Groundwater; Soil profile; Water table

INFORM

INFORM was founded in 1973 by environmental research specialist Joanna Underwood and two colleagues. Seriously concerned about **air pollution**, the three scientists decided to establish an organization that would identify practical ways to protect the **environment** and public health. Since then, their concerns have widened to include **hazardous waste**, solid **waste management**, **water pollution**, and land, energy, and **water conservation**. The group's primary purpose is "to examine business practices which harm our air, water, and land resources" and pinpoint "specific ways in which practices can be improved."

INFORM's research is recognized throughout the United States as instrumental in shaping environmental policies and programs. Legislators, **conservation** groups and business leaders use INFORM's authority as an acknowledged basis for research and conferences. Source reduction has become one of INFORM's most important projects. A decrease in the amount and/or toxicity of waste entering the **waste stream**, source reduction includes any activity by an

individual, business, or government that lessens the amount of solid waste—or garbage—that would otherwise have to be recycled or incinerated. Source reduction does not include **recycling**, **municipal solid waste composting**, household hazardous waste collection, or beverage container deposit and return systems.

The first priority in source reduction strategies is elimination; the second, **reuse**. Public education is a crucial part of INFORM's program. To this end INFORM has published *Making Less Garbage: A Planning Guide for Communities*. This book details ways to achieve source reduction including buying reusable, as opposed to disposable, items; buying in bulk; and maintaining and repairing products to extend their lives.

INFORM's outreach program goes well beyond its source reduction project. The staff of over 25 full-time scientists and researchers and 12 volunteers and interns makes presentations at national and international conferences and local workshops. INFORM representatives have also given briefings and testimony at Congressional hearings and produced television and radio advertisements to increase public awareness on environmental issues. The organization also publishes a quarterly newsletter, *INFORM Reports*.

INFOTERRA (U.N. Environment Program)

INFOTERRA has its international headquarters in Kenya and is a global information network operated by the **Earthwatch** program of the United Nations Environment Program (UNEP).

Under INFOTERRA, participating nations designate institutions to be national focal points, such as the **Environmental Protection Agency** (EPA) in the United States. Each national institution chosen as a focal point, prepares a list of its national environmental experts and selects what it considers the best sources for inclusion in INFOTERRA's international directory of experts.

INFOTERRA initially used its directory only to refer questioners to the nearest appropriate experts, but the organization has evolved into a central information agency. It consults sources, answers public queries for information, and analyzes the replies. INFOTERRA is used by governments, industries, and researchers in 177 countries.

Injection well

Injection **wells** are used to dispose waste into the subsurface zone. These wastes can include brine from oil and gas wells, liquid hazardous wastes, agricultural and **urban runoff**, municipal sewage, and return water from air-conditioning. Recharge wells can also be used for injecting fluids to enhance oil recovery, injecting treated water for artificial **aquifer** recharge, or enhancing a pump-and-treat system. If the wells are poorly designed or constructed, or if the local geology is not sufficiently studied, injected liquids can enter an aquifer and cause **groundwater** contamination. Injection wells are regulated under the Underground Injection Control Program of the **Safe Drinking Water Act**. *See also* Aquifer restoration; Deep-well injection; Drinking-water supply; Groundwater monitoring; Groundwater pollution; Water table

Inoculate

To inoculate involves the introduction of **microorganisms** into a new **environment**. Originally the term referred to the insertion of a bud or shoot of one plant into the stem or trunk of another to develop new strains or hybrids. These hybrid plants would be resistant to botanic disease or they would allow greater harvests or range of climates. With the advent of vaccines to prevent human and animal disease, the term inoculate has come to represent injection of a serum to prevent, cure, or make immune from disease.

Inoculation is of prime importance in that the introduction of specific microorganism **species** into specific macroorganisms may establish a symbiotic relationships where each organism benefits. For example, the introduction of **mycorrhiza** fungus to plants improves the plants' ability to absorb nutrients from the **soil**. *See also* Symbiosis

Insecticide

see **Pesticide**

Integrated pest management

Integrated **pest** management (IPM) is a newer science that aims to give the best possible pest control while minimizing damage to human health or the **environment**. IPM means either using fewer **chemicals** more effectively or finding ways, both new and old, that substitute for **pesticide** use.

Technically, IPM is the selection, integration and implementation of pest control based on predicted economic, ecological and sociological consequences. IPM seeks maximum use of naturally occurring pest controls, including weather, disease agents, predators and **parasites**. In addition, IPM utilizes various biological, physical, and chemical control and **habitat** modification techniques. Artificial controls are imposed only as required to keep a pest from surpassing intolerable population levels which are predetermined from assessments of the pest damage potential and the ecological, sociological, and economic costs of the control measures. Farmers have come to understand that the presence of a pest **species** does not necessarily justify action for its control. In fact, tolerable infestations may be actually desirable, providing food for important beneficial insects. Why this change in farming practices?

The introduction of synthetic organic pesticides such as the insecticide DDT, and the **herbicide 2,4-D** (half the formula in **Agent Orange**) after World War II began a new era in pest control. These products were followed by hundreds of synthetic organic fungicides, nematicides, rodenticides and other chemical controls. These chemical materials were initially very effective and very cheap. Synthetic chemicals eventually became the primary means of pest control in productive agricultural regions, providing season-long crop protection against insects and weeds. They were used in addition to fertilizers and other treatments.

The success of modern pesticides led to widespread acceptance and reliance upon them, particularly in this country. Of all the chemical pesticides applied worldwide in agriculture, forests, industry and households, one-third to one-half were used in the United States. Herbicides have been used increasingly to replace hand labor and machine cultivation for control of weeds in crops, in forests, on the rights-of-way of highways, utility lines, railroads and in cities. Agriculture consumes perhaps 65% of the total quantity of synthetic organic pesticides used in the United States each year. In addition, chemical companies export an increasingly larger amount to **Third World** countries. Pesticides banned in the United States such as DDT, EDB and **chlordane**, are exported to countries where they are applied to crops imported by the United States for consumption.

For more than a decade, problems with pesticides have become increasingly apparent. Significant groups of pests have evolved with **genetic resistance** to pesticides. The increase in **resistance** among insect pests has been exponential, following extensive use of chemicals in the last forty years. Ticks, insects and spider mites (nearly 400 species) are now especially resistant, and the creation of new insecticides to combat the problem is not keeping pace with the emergence of new strains of resistant insect pests. Despite the advances in modern chemical control and the dramatic increase in chemical pesticides used on U.S. cropland, annual crop losses from all pests appear to have remained constant or to have increased. Losses caused by weeds have declined slightly, but those caused by insects have nearly doubled. The price of synthetic organic pesticides has increased significantly in recent years, placing a heavy financial burden on those who use large quantities of the materials. As farmers and growers across the United States realize the limitations and human health consequences of using artificial chemical pesticides, interest in the alternative approach of integrated pest management grows.

Integrated pest management aims at management rather than eradication of pest species. Since potentially harmful species will continue to exist at tolerable levels of abundance, the philosophy now is to manage rather than eradicate the pests. The **ecosystem** is the management unit. (Every crop is in itself a complex ecological system.) Spraying pesticides too often, at the wrong time, or on the wrong part of the crop may destroy the pests' natural enemies ordinarily present in the ecosystem. Knowledge of the actions, reactions, and interactions of the components of the ecosystems is requisite to effective IPM programs. With this knowledge, the ecosystem is manipulated in order to hold pests at tolerable levels while avoiding disruptions of the system.

The use of natural controls is maximized. IPM emphasizes the fullest practical utilization of the existing regulating and limiting factors in the form of parasites, predators, and weather, which check the pests' **population growth**. IPM users understand that control procedures may produce unexpected and undesirable consequences, however. It takes time to change over and determination to keep up the commitment until the desired results are achieved.

An interdisciplinary systems approach is essential. Effective IPM is an integral part of the overall management of a farm, a business or a forest. For example, timing plays an important role. Certain pests are most prevalent at particular times of the year. By altering the date on which a crop is planted, serious pest damage can be avoided. Some farmers simultaneously plant and harvest, since the procedure prevents the pests from migrating to neighboring fields after the harvest. Others may plant several different crops in the same field, thereby reducing the number of pests. The variety of crops harbor greater numbers of natural enemies and make it more difficult for the pests to locate and colonize their

host plants. In Thailand and China, farmers flood their fields for several weeks before planting to destroy pests. Other farmers turn the **soil**, so that pests are brought to the surface and die in the sun's heat.

The development of specific IPM program depends on the pest complex, resources to be protected, economic values, and availability of personnel. It also depends upon adequate funding for research and to train farmers. Some of the techniques are complex, and expert advice is needed. However, while it is difficult to establish absolute guidelines, there are general guidelines that can apply to the management of any pest group.

Growers must analyze the "pest" status of each of the reputedly injurious organisms and establish economic thresholds for the "real" pests. The economic threshold is, in fact, the population level, and is defined as the density of a pest population below which the cost of applying control measures exceeds the losses caused by the pest. Economic threshold values are based on assessments of the pest damage potential and the ecological, sociological, and economic costs associated with control measures. A given crop, forest area, backyard, building, or recreational area may be infested with dozens of potentially harmful species at any one time. For each situation, however, there are rarely more than a few pest species whose populations expand to intolerable levels at regular and fairly predictable intervals. Key pests recur regularly at population densities exceeding economic threshold levels and are the focal point for IPM programs.

Farmers must also devise schemes for lowering equilibrium positions of key pests. A key pest will vary in severity from year to year, but its average density, known as the equilibrium position, usually exceeds its economic threshold. IPM efforts manipulate the environment in order to reduce a pest's equilibrium position to a permanent level below the economic threshold. This reduction can be achieved by deliberate introduction and establishment of natural enemies (parasites, predators, and diseases) in areas where they did not previously occur. Natural enemies may already occur in the crop in small numbers or can be introduced from elsewhere. Certain **microorganisms**, when eaten by a pest, will kill it.

Newer chemicals show promise as alternatives to synthetic chemical pesticides. These include insect attractant chemicals, weed and insect disease agents and insect growth regulators or hormones. A **pathogen** such as **Bacillus thuringiensis** (BT), has proven commercially successful. Since certain crops have an inbuilt resistance to pests, pest-resistant or pest-free varieties of seed, crop plants, ornamental plants, orchard trees, and forest trees can be used. Growers can also modify the pest environment to increase the effectiveness of the pest's biological control agents, to destroy its breeding, feeding, or shelter habitat or otherwise render it harmless. This includes crop rotation, destruction of crop harvest residues and soil tillage, and selective burning or mechanical removal of undesirable plant species and pruning, especially for forest pests.

While nearly permanent control of key insect and plant disease pests of agricultural crops has been achieved, emergencies will occur, and all IPM advocates acknowledge this. During those times, measures should be applied that create the least ecological destruction. Growers are urged to utilize the best combination of the three basic IPM components: natural enemies, resistant varieties and environmental modification. However, there may be a time when pesticides may be the only recourse. In that case, it is important to coordinate the proper pesticide, the dosage and the timing in order to minimize the hazards to nontarget organisms and the surrounding ecosystems.

Pest management techniques have been known for many years and were used widely before World War II. They were deemphasized by insect and weed control scientists and by corporate pressures as the synthetic chemicals became commercially available after the war. Now there is a renewed interest in the early control techniques and in new chemistry.

Reports detailing the success of IPM are emerging at a rapid rate as thousands of farmers yearly join the ranks of those who choose to eliminate chemical pesticides. Sustainable agricultural practice increases the richness of the soil by replenishing the soil's reserves of fertility. IPM does not produce secondary problems such as pest resistance or resurgence. It also diminishes soil **erosion**, increases crop yields and saves money over the long haul. Organic foods are reported to have better cooking quality, better flavor and greater longevity in the storage bins. And with less **pesticide residue**, our food is clearly more healthy to eat. *See also* Sustainable agriculture

Intergenerational justice

One of the key features of an environmental ethic or perspective is its concern for the health and well-being of **future generations**. Questions about the rights of future people and the responsibilities of those presently living are central to environmental theory and practice and are often asked and analyzed under the term *intergenerational justice*. Most traditional accounts or theories of justice have focused on relations between contemporaries: What distribution of scarce goods is fairest or optimally just? Should such goods be distributed on the basis of merit or need? These and other questions have been asked by thinkers from Aristotle through John Rawls. Recently, however, some philosophers have begun to ask about just distributions over time and across generations.

The subject of intergenerational justice is a key concern for environmentally-minded thinkers for at least two reasons. First, human beings now living have the power to permanently alter or destroy the planet (or portions thereof) in ways that will affect the health, happiness, and well-being of people living long after we are all dead. One need only think, for example, of the radioactive wastes generated by nuclear **power plants** which will be intensely "hot" and dangerous for many thousands of years. No one yet knows how to safely store such material for a hundred, much less many thousands, of years. Considered from an intergenerational perspective then, it would be unfair—that is, unjust—for the present generation to enjoy the benefits of **nuclear power**, passing on to distant posterity the burdens and dangers caused by our (in)action.

Second, we not only have the power to affect future generations, but we *know* that we have it. And with such knowledge comes the moral responsibility to act in ways that will prevent harm to future people. For example, since we know about the health effects of radiation on human beings, our having that knowledge imposes upon us a moral obligation not to needlessly expose anyone—now or in the indefinite future—to the harms or hazards of radioactive wastes. Many other examples of intergenerational harm or hazard exist: global warming, **topsoil erosion**, disappearing tropical rain forests, depletion and/or **pollution** of aquifers, among others. But whatever the example, the point of the intergenerational view is the same: the moral duty to treat people justly or fairly applies not only to people now living, but to those who will live long after we are gone. To the extent that our actions produce consequences that may prove harmful to people who have not harmed (and in the nature of the case cannot harm) us is, by any standard, unjust. And yet it seems quite clear that we in the present generation are in many respects acting unjustly toward distant posterity. This is true not only for harms or hazards bequeathed to future people, but the point applies also to deprivations of various kinds.

Consider, for example, the present generation's profligate use of **fossil fuels**. Reserves of oil and **natural gas** are both finite and nonreplaceable; once burned (or turned into plastic or some other petroleum-based material), a gallon of oil is gone forever; every drop or barrel used now is therefore unavailable for future people. As Wendell Berry observed, the claim that fossil fuel energy is *cheap* rests on a simplistic and morally doubtful assumption about the *rights* of the present generation: "We were able to consider [fossil fuel energy] "cheap" only by a kind of moral simplicity: the assumption that we had a "right" to as much of it as we could use. This was a "right" made solely by might. Because fossil fuels, however abundant they once were, were nevertheless limited in quantity and not renewable, they obviously did not "belong" to one generation more than another. We ignored the claims of posterity simply because we could, the living being stronger than the unborn, and so worked the "miracle" of industrial progress by the theft of energy from (among others) our children."

And that, Berry adds, "is the real foundation of our progress and our affluence. The reason that we are a rich nation is not that we have earned so much wealth — you cannot, by any honest means, earn or deserve so much. The reason is simply that we have learned, and become willing, to market and use up in our own time the birthright and livelihood of posterity."

These and other considerations have led some environmentally-minded philosophers to argue for limits on present-day consumption, so as to save a fair share of scarce resources for future generations. John Rawls, for instance, constructs a *just savings principle* according to which members of each generation may consume no more than their fair share of scarce resources. The main difficulty in arriving at and applying any such principle lies in determining what counts as fair share. As the number of generations taken into account increases, the share available to any single generation then becomes smaller; and as the number of generations approaches infinity, any one generation's share approaches zero.

Other objections have been raised against the idea of intergenerational justice. These objections can be divided into two groups, which we can call conceptual and technological. One conceptual criticism is that the very idea of intergenerational justice is itself incoherent. The idea of justice is tied with that of reciprocity or exchange; but relations of reciprocity can exist only between contemporaries; therefore the concept of justice is inapplicable to relations between existing people and distant posterity. Future people are in no position to reciprocate; therefore people now living cannot be morally obligated to do anything for them. An-

other conceptual objection to the idea of intergenerational justice is concerned with rights. Briefly, the objection runs as follows: future people do not (yet) exist; only actually existing people have rights, including the right to be treated justly; therefore future people do not have rights which we in the present have a moral obligation to respect and protect. Critics of this view counter that it not only rests on a too-restrictive conception of rights and justice, but that it also paves the way for grievous intergenerational injustices.

Several arguments can be constructed to counter the claim that justice rests on reciprocity (and therefore applies only to relations between contemporaries) and the claim that future people do not have rights, including the right to be treated justly by their predecessors. Regarding reciprocity: since we acknowledge in ethics and recognize in law that it is possible to treat an infant or a mentally disabled or severely retarded person justly or unjustly, even though they are in no position to reciprocate, it follows that the idea of justice is not necessarily connected with reciprocity. Regarding the claim that future people cannot be said to have rights that require our recognition and respect: one of the more ingenious arguments against this view consists of modifying John Rawls's imaginary *veil of ignorance*. Rawls argues that principles of justice must not be partisan or favor particular people but must be blind and impartial. To ensure impartiality in arriving at principles of justice, Rawls invites us to imagine an original position in which rational people are placed behind a veil of ignorance wherein they are unaware of their age, race, sex, social class, economic status, etc. Unaware of their own particular position in society, rational people would arrive at and agree upon impartial and universal principles of justice. To ensure that such impartiality extends across generations, one need only *thicken* the veil by adding the proviso that the choosers be unaware of the generation to which they belong. Rational people would not accept or agree to principles under which predecessors could harm or disadvantage successors.

Some critics of intergenerational justice argue in technological terms. They contend that existing people need not restrict their consumption of scarce or **nonrenewable resources** in order to save some portion for future generations. For, they argue, substitutes for these resources will be discovered or devised through technological innovations and inventions. For example, as fossil fuels become scarcer and more expensive, new fuels—gasohol or fusion-derived nuclear fuel—will replace them. Thus we need never worry about depleting any particular resource because every resource can be replaced by a substitute that is as cheap, clean, and accessible as the resource it replaces. Likewise, we need not worry about generating nuclear wastes that we do not yet know how to store safely. Some solution is bound to be devised sometime in the future.

Environmentally-minded critics of this technological line of argument claim that it amounts to little more than wishful thinking. Like Charles Dickens's fictional character Mr. Micawber, those who place their faith in technological solutions to all environmental problems optimistically expect that "something will turn up." Just as Mr. Micawber's faith was misplaced, so too, these critics contend, is the optimism of those who expect technology to solve all problems, present and future. Of course such solutions may be found, but that is a gamble and not a guarantee. To wager with the health and well-being of future people is, environmentalists argue, immoral.

There are of course many other issues and concerns raised in connection with intergenerational justice. Discussions among and disagreements between philosophers, economists, environmentalists, and others are by no means purely abstract and academic. How these matters are resolved will have a profound effect on the fate of future generations.

Intergovernmental Panel on Climate Change (IPCC)

The Intergovernmental Panel on Climate Change (IPCC) was established in 1988 as a joint project of the **United Nations Environment Programme** (UNEP) and the World Meteorological Organization (WMO). The primary mission of the IPCC is to bring together the world's leading experts on the earth's climate to gather, assess, and disseminate scientific information about climate change, with a view to informing international and national policy makers. The

IPCC has become the highest-profile and best-regarded international agency concerned with the climatic consequences of "greenhouse gases," such as **carbon dioxide** and **methane**, that are a byproduct of the **combustion** of **fossil fuels**. The IPCC is an organization that has been and continues to be at the center of a great deal of controversy.

The IPCC was established partly in response to Nobel Laureate Mario Molina's 1985 documentation of chemical processes which occur when human-made **chemicals** deplete the earth's atmospheric **ozone** shield. Ozone depletion is likely to result in increased levels of **ultraviolet radiation** reaching the earth's surface, producing a host of health, agricultural, and environmental problems. Molina's work helped to persuade most of the industrialized nations to ban **chlorofluorocarbons** and several other ozone-depleting chemicals. It also established a context in which national and international authorities began to pay serious attention to the global environmental consequences of atmospheric changes resulting from industrialization and reliance on fossil fuels.

Continuing to operate under the auspices of the United Nations and headquartered in Geneva, Switzerland, the IPCC is organized into three working groups and a task force, and meets about once a year. The first group gathers scientific data and analyzes the functioning of the climate system with special attention to the detection of potential changes resulting from human activity. The second group's assignment is to assess the potential socioeconomic impacts and vulnerabilities associated with climate change. It is also charged with exploring options for humans to adapt to potential climate change. The third group focuses on ways to reduce greenhouse gas emissions and to stop or reduce climate change. The task force is charged with maintaining inventories of greenhouse emissions for all countries.

The IPCC has published its major findings in "Full Assessment" Reports, first issued in 1990 and 1995. The Tenth Session of the IPCC (Nairobi, 1994) directed that future full assessments should be prepared approximately every five years. The Third Assessment Report was entitled "Climate Change 2001". Special reports and technical papers are also published as the panel identifies issues.

The IPCC has drawn a great deal of criticism virtually from its inception. Massive amounts of money are at stake in policy decisions which might seek to limit greenhouse gas emissions, and much of the criticism directed at the IPCC tends to come from lobbying and research groups mostly funded by industries that either produce or use large quantities of fossil fuels. Thus, a lobbying group sponsored by energy, **transportation**, and manufacturing interests called the Global Climate Coalition attacked parts of the 1995 report as unscientific. At the core of the controversy was Chapter Eight of the report, "Detection of Climate Change and Attribution of Causes". Although the IPCC was careful to hedge its conclusions in various ways, acknowledging difficulties in measurement, disagreements over methodologies for interpreting data, and general uncertainty about the conclusions of its findings, it nevertheless suggested a connection between greenhouse gas emissions and global warming. Not satisfied with such caveats, the Global Climate Coalition charged that the IPCC's conclusions had been presented as far less debatable than they actually were. This cast a cloud of uncertainty over the report, at least for some United States policymakers. However, other leaders took the report more seriously. The Second Assessment Report provided important input to the negotiations that led to the development of the Kyoto Protocol in 1997, a treaty aimed at reducing the global output of **greenhouse gases**.

In the summer of 1996, results of new studies of the upper **atmosphere** were published which provided a great deal of indirect support for the IPCC's conclusions. Investigators found significant evidence of cooling in the upper atmosphere and warming in the lower atmosphere, with this effect being especially pronounced in the southern hemisphere. These findings confirmed the predictions of global warming models such as those employed by the IPCC.

Perhaps emboldened by this confirmation, but still facing a great deal of political opposition, the IPCC released an unequivocal statement about global warming and its causes in November 1996. The IPCC declared that "the balance of evidence suggests that there is a discernible human influence on global climate". The statement made clear that a preponderance of evidence and a majority of scientific experts indicated that observable climate change was a result of human activity. The IPCC urged that all nations limit their use of fossil fuels and develop more energy-efficient technologies.

These conclusions and recommendations provoked considerable criticism from less-developed countries. Leaders of the less-industrialized areas of the world tend to view potential restrictions on the use of fossil fuels as unfair hindrance of their efforts to catch up with the United States and Western Europe in industry, transportation, economic infrastructure, and standards of living. The industrialized nations, they point out, were allowed to develop without any such restrictions and now account for the vast majority of the world's energy consumption and greenhouse gas emissions. These industrialized nations therefore should bear the brunt of any efforts to protect the global climate, substantially exempting the developing world from restrictions on the use of fossil fuels.

The IPCC's conclusions and recommendations have also drawn strong opposition from industry groups in the United States, such as the American **Petroleum** Institute,

and conservative Republican politicians. These critics charge that the IPCC's new evidence is only fashionable but warmed-over theory, and that no one has yet proven conclusively that climate change is indeed related to human influence. In view of the likely massive economic impact of any aggressive program aimed at the reduction of emissions, there is no warrant for following the IPCC's dangerous and ill-considered advice. Under Republican leadership, Congress slashed funds for **Environmental Protection Agency** and Department of Energy programs concerned with global warming and its causes, as well as funds for researching alternative and cleaner sources of energy.

These funding cuts and the signals they sent created foreign relations problems for the Clinton Administration. The United States was unable to honor former President Bush's 1992 pledge (at the Rio de Janeiro Earth Summit) to reduce the country's **emission** of **carbon** dioxide and methane to 1990 levels by the year 2000. Indeed, owing in part to low oil prices and a strong domestic economy, the United States was consuming more energy and emitting more greenhouse gases than ever before by 2000.

In the summer of 2001, the IPCC released its strongest statement to date on the problem of global warming, in its Third Assessment Report. The report, "Climate Change 2001", provides further evidence for global warming and its cause—the widescale burning of fossil fuels by humans. The report projects that global mean surface temperatures on earth will increase by 2.5–10.4°F (1.5–5.9°C) by the year 2100, unless greenhouse gas emissions are reduced well below current levels. The report also notes that this warming trend will represent the fasting warming of the earth in 10,000 years, with possible dire consequences to human society and the **environment**.

In the early 2000s, the administration of President George W. Bush, a former oilman, was resistant to the ideas of global warming and reducing greenhouse gas emissions. The administration strongly opposed the Kyoto Treaty and domestic **pollution** reduction laws, claiming such measures would cost jobs and reduce the standard of living, and that the scientific evidence was inconclusive. In June 2001, a National Academy of Science (NAS) panel reported to President Bush that the IPCC's studies on global warming were scientifically valid. In April 2002, with pressure from the oil industry, the Bush administration forced the removal of IPCC Chairman Robert Watson, an American atmospheric scientist who had been outspoken over the issue of climate change and the need for greenhouse gas reduction in industrialized countries.

The IPCC elected Dr. Rajendra K. Pachauri as its next Chairman at its nineteenth session in Geneva. Dr. Pachauri, a citizen of India, is a well-known world-class expert in economics and technology, with a strong commitment to the IPCC process and to scientific integrity.

Internal costs

see **Internalizing costs**

Internalizing costs

Private market activities create so-called externalities. An example of a negative **externality** is **air pollution**. It occurs when a producer does not bear all the costs of an activity in which he or she engages. Since external costs do not enter into the calculations producers make, they will make few attempts to limit or eliminate **pollution** and other forms of **environmental degradation**.

Negative externalities are a type of market defect all economists believe is appropriate to try to correct. Milton Friedman refers to such externalities as "neighborhood effects," (although it must be kept in mind that some forms of pollution have an all but local effect). The classic neighborhood effect is pollution. The premise of a free market is that when two people voluntarily make a deal, they both benefit. If society gives everyone the right to make deals, society as a whole will benefit. It becomes richer from the aggregation of the many mutually beneficial deals that are made. However, what happens if in making mutually beneficial deals there is a waste product that the parties release

into the **environment** and that society must either suffer from or clean up? The two parties to the deal are better off, but society as a whole has to pay the costs. Friedman points out that individual members of a society cannot appropriately charge the responsible parties for external costs or find other means of redress.

Friedman's answer to this dilemma is simple: society, through government, must charge the responsible parties the costs of the clean-up. Whatever damage they generate must be internalized in the price of the transaction. Polluters can be forced to internalize environmental costs through pollution taxes and **discharge** fees, a method generally favored by economists. When such taxes are imposed, the market defect (the price of pollution which is not counted in the transaction) is corrected. The market price then reflects the true social costs of the deal, and the parties have to adjust accordingly. They will have an incentive to decrease harmful activities and develop less environmentally damaging technology. The drawback of such a system is that society will not have direct control over pollution levels, although it will receive monetary compensation for any losses it sustains. However, if the government imposed a tax or charge on the polluting parties, it would have to place a monetary value on the damage. In practice, this is difficult to do. How much for a human life lost to pollution? How much for a vista destroyed? How much for a plant or animal **species** brought to **extinction**? Finally, the idea that pollution is all right as long as the polluter pays for it is unacceptable to many people.

In fact, the government has tried to control activities with associated externalities through regulation, rather than by supplementing the price system. It has set standards for specific industries and other social entities. The standards are designed to limit environmental degradation to acceptable levels and are enforced through the **Environmental Protection Agency** (EPA). They prohibit some harmful activities, limit others, and prescribe alternative behaviors. When market actors do not adhere to these standards they are subject to penalties. In theory, potential polluters are given incentives to reduce and treat their waste, manufacture less harmful products, develop alternative technologies, and so on. In practice, the system has not worked as well as it was hoped in the 1960s and 1970s, when much of the environmental legislation presently in force was enacted. Enforcement has been fraught with political and legal difficulties. Extensions on deadlines are given to cities for not meeting clean air standards and to the **automobile** industry for not meeting standards on fuel economy of new cars, for instance. It has been difficult to collect fines from industries found to have been in violation. Many cases are tied up in the courts through a lengthy appeals process. Some companies simply declare bankruptcy to evade fines. Others continue polluting because they find it cheaper to pay fines than to develop alternative production processes.

Alternative strategies presently under debate include setting up a **trade in pollution permits**. The government would not levy a tax on pollution but would issue a number of permits that altogether set a maximum acceptable pollution level. Buyers of permits can either use them to cover their own polluting activities or resell them to the highest bidder. Polluters will be forced to internalize the environmental costs of their activities so that they will have an incentive to reduce pollution. The price of pollution will then be determined by the market. The disadvantage of this system is that the government will have no control over where pollution takes place. It is thinkable that certain regions will have high concentrations of industries using the permits, which may result in local pollution levels that are unacceptably high. Whether marketable pollution permits address present pollution problems more satisfactorily than does regulation alone has yet to be seen. *See also* Environmental economics

International Atomic Energy Agency

The first decade of research on **nuclear weapons** and nuclear reactors was characterized by extreme secrecy, and the few nations that had the technology carefully guarded their information. In 1954, however, that philosophy changed, and the United States, in particular, became eager to help other nations use nuclear energy for peaceful purposes. A program called "Atoms for Peace" brought foreign students to the United States for the study of nuclear sciences and provided enriched **uranium** to countries wanting to build their own reactors, encouraging interest in nuclear energy throughout much of the world.

But this program created a problem. It increased the potential diversion of nuclear information and nuclear materials for the construction of weapons, and the threat of nuclear proliferation grew. The United Nations created the International Atomic Energy Agency (IAEA) in 1957 to address this problem. The agency had two primary objectives: to encourage and assist with the development of peaceful applications of **nuclear power** throughout the world and to prevent the diversion of nuclear materials to weapons research and development.

The first decade of IAEA's existence was not marked by much success. In fact, the United States was so dissatisfied with the agency's work that it began signing bilateral non-proliferation treaties with a number of countries. Finally, the 1970 nuclear non-proliferation treaty more clearly designated the IAEA's responsibilities for the monitoring of nuclear material.

Today the agency is an active division of the United Nations Educational, Scientific, and Cultural Organization (UNESCO), and its headquarters are in Vienna. The IAEA operates with a staff of more than 800 professional workers, about 1,200 general service workers, and a budget of about $150 million. To accomplish its goal of extending and improving the peaceful use of nuclear energy, IAEA conducts regional and national workshops, seminars, training courses, and committee meetings. It publishes guidebooks and manuals on related topics and maintains the International Nuclear Information System, a bibliographic database on nuclear literature that includes more than 1.2 million records. The database is made available on magnetic tape to its 42-member states.

The IAEA also carries out a rigorous program of inspection. In 1987, for example, it made 2,133 inspections at 631 nuclear installations in 52 non-nuclear weapon nations and four nuclear weapon nations. In a typical year, IAEA activities include conducting safety reviews in a number of different countries, assisting in dealing with accidents at nuclear **power plants**, providing advice to nations interested in building their own nuclear facilities, advising countries on methods for dealing with radioactive wastes, teaching nations how to use radiation to preserve foods, helping universities introduce nuclear science into their curricula, and sponsoring research on the broader applications of nuclear science.

International Cleaner Production Cooperative

The International Cleaner Production Cooperative is an Internet resource (<http://es.epa.gov/cooperative/international>) that was implemented to provide access to globally relevant information about cleaner production and **pollution** prevention to the international community. The site is hosted by the U.S. **Environmental Protection Agency** and gives access to a consortium of World Wide Web sites that provides information to businesses, professional, and local, regional, national, and international agencies that are striving for cleaner production. The cooperative provides links to people and businesses involved with cleaner production and pollution prevention, and to sources of technical assistance and information on international policy. The **United Nations Environment Programme** (UNEP) is one of the primary members of the cooperative.

[*Marie H. Bundy*]

International Convention for the Regulation of Whaling (1946)

The International **Whaling** Commission (IWC) was established in 1949 following the inaugural International Convention for the Regulation of Whaling, which took place in Washington, D.C., in 1946. Many nations have membership in the IWC, which primarily sets quotas for **whales**. The purpose of these quotas is twofold: they are intended to protect the whale **species** from **extinction** while allowing a limited whaling industry. In recent times, however, the IWC has come under attack. The vast majority of nations in the Commission have come to oppose whaling of any kind and object to the IWC's practice of establishing quotas. Furthermore, some nations—principally Iceland, Japan, and Norway—wish to protect their traditional whaling industries and are against the quotas set by the IWC. With two such divergent factions opposing the IWC, its future is as doubtful as that of the whales.

Since its inception, the Commission has had difficulty implementing its regulations and gaining approval for its recommendations. In the meantime whale populations have continued to dwindle. In its original design, the IWC consisted of two sub-committees, one scientific and the other technical. Any recommendation that the scientific committee put forth was subject to the politicized technical committee before final approval. The technical committee evaluated the recommendation and changed it if it was not politically or economically viable; essentially, the scientific committee's recommendations have often been rendered powerless. Furthermore, any nation that has decided an IWC recommendation was not in its best interest could have dismissed it by simply registering an objection. In the 1970s this gridlock and inaction attracted public scrutiny; people objected to the IWC's failure to protect the world's whales. Thus in 1972 the **United Nations Conference on the Human Environment** voted overwhelmingly to stop commercial whaling.

Nevertheless, the IWC retained some control over the whaling industry. In 1974 the Commission attempted to bring scientific research to management strategies in its

"New Management Procedure." The IWC assessed whale populations with finer resolution, scrutinizing each species to see if it could be hunted and not die out. It classified whales as either "initial management stocks" (harvestable), "sustained management stocks" (harvestable), or "protection stocks" (unharvestable). While these classifications were necessary for effective management, much was unknown about whale population **ecology**, and quota estimates contained high levels of uncertainty.

Since the 1970s, public pressure has caused many nations in the IWC to oppose whale **hunting** of any kind. At first, one or two nations proposed a whaling moratorium each year. Both pro- and anti-whaling countries began to encourage new IWC members to vote for their respective positions, thus dividing the Commission. In 1982, the IWC enacted a limited moratorium on commercial whaling, to be in effect from 1986 until 1992. During that time it would thoroughly assess whale stocks and afterward allow whaling to resume for selected species and areas. Norway and Japan, however, attained special permits for whaling for scientific research: they continued to catch approximately 400 whales per year, and the meat was sold to restaurants. Then in 1992—the year when whaling was supposed to have resumed—many nations voted to extend the moratorium. Iceland, Norway, and Japan objected strongly to what they saw as an infringement on their traditional industries and eating customs. Iceland subsequently left the IWC, and Japan and Norway have threatened to follow. These countries intend to resume their whaling programs. Members of the IWC are torn between accommodating these nations in some way and protecting the whales, and amid such controversy it is unlikely that the Commission can continue in its present mission.

Although the IWC has not been able to marshall its scientific advances or enforce its own regulations in managing whaling, it is broadening its original mission. The Commission may begin to govern the hunting of small cetaceans such as **dolphins** and porpoises, which are believed to suffer from **overhunting**.

International Geosphere-Biosphere Programme (U.N. Environmental Programme)

Research scientists from all countries have always interacted with each other closely. But in recent decades, a new type of internationalism has begun to evolve, in which scientists from all over the world work together on very large projects concerning the planet.

An example is research on global change. A number of scientists have come to believe that human activities, such as the use of **fossil fuels** and **deforestation** of tropical rain forests, may be altering the earth's **climate**. To test that hypothesis, a huge amount of meteorological data must be collected from around the world, and no single institution can possibly obtain and analyze it all.

A major effort to organize research on important, worldwide scientific questions such as climate change was begun in the early 1980s. Largely through the efforts of scientists from two United States organizations, the National Aeronautics and Space Administration (NASA) and the **National Research Council**, a proposal was developed for the creation of an International Geosphere-Biosphere Programme (IGBP). The purpose of the IGBP was to help scientists from around the world focus on major issues about which there was still too little information. Activity funding comes from national governments, scientific societies, and private organizations.

IGBP was not designed to be a new organization, with new staff, new researchers, and new funding problems. Instead, it was conceived of as a coordinating program that would call on existing organizations to attack certain problems. The proposal was submitted in September 1986 to the General Assembly of the International Council of Scientific Unions (ICSU), where it received enthusiastic support.

Within two years, more than 20 nations agreed to cooperate with IGBP, forming national committees to work with the international office. A small office, administered by Harvard oceanographer James McCarthy, was installed at the Royal Swedish Academy of Sciences in Stockholm.

IGBP has moved forward rapidly. It identified existing programs that fit the Programme's goals and developed new research efforts. Because many global processes are gradual, a number of IGBP projects are designed with time frames of ten to twenty years.

By the early 1990s, IGBP had defined a number of projects, including the Joint Global Ocean Flux Study, the Land-Ocean Interactions in the Coastal Zone study, the Biospheric Aspects of the Hydrological Cycle research, Past Global Changes, Global Analysis, Interpretation and **Modeling**, and Global Change System for Analysis, Research and Training.

International Institute for Sustainable Development

The International Institute for **Sustainable Development** (IISD) is a nonprofit organization that serves as an information and resources clearinghouse for policy makers promoting sustainable development. IISD aims to promote sustainable development in decision making worldwide by assisting with policy analysis, providing information about practices, measuring sustainability, and building partnerships to further sustainability goals. It serves businesses, governments, communities, and individuals in both developing and industrialized nations. IISD's stated aim is to "create networks designed to move sustainable development from concept to practice." Founded in 1990 and based in Winnipeg, Canada, IISD is funded by foundations, governmental organizations, private sector sources, and revenue from publications and products.

IISD works in seven program areas. The Business Strategies program focuses on improving competitiveness, creating jobs, and protecting the **environment** through sustainability. Projects include several publications and the EarthEnterprise program, which offers entrepreneurial and employment strategies. IISD's Trade and Sustainable Development program works on building positive relationships between trade, the environment, and development. It examines how to make international accords, such as those made by the **World Trade Organization**, compatible with the goals of sustainable development. The Community **Adaptation** and Sustainable Livelihoods program identifies adaptive strategies for drylands in Africa and India, and it examines the influences of policies and new technology on local ways of life. The Great Plains program works with community, farm, government, and industry groups to assist communities in the Great Plains region of North America with sustainable development. It focuses on government policies in agriculture, such as the Western Grain **Transportation** Act, as well as loss of transportation subsidies, the **North American Free Trade Agreement** (NAFTA), **soil** salination and loss of **wetlands**, job loss, and technological advances. Measurement and Indicators aims to set measurable goals and progress indicators for sustainable development. As part of this, IISD offers information about the successful uses of taxes and subsidies to encourage sustainability worldwide. Common Security focuses on initiatives of peace and consensus-building.

IISD's Information and Communications program offers several publications and Internet sites featuring information on sustainable development issues, terms, events, and media coverage. This includes *Earth Negotiations Bulletin*, which provides on-line coverage of major environmental and development negotiations (especially United Nations conferences), and IISDnet, with information about sustainable development worldwide. IISD also publishes more than 50 books, monographs, and discussion papers, including *Sourcebook on Sustainable Development*, which lists organizations, databases, conferences, and other resources. IISD produces five journals that include *Developing Ideas*, published bimonthly both in print and electronically, and featuring articles on sustainable development terms, issues, resources, and recent media coverage. *Earth Negotiations Bulletin* reports on conferences and negotiations meetings, especially United Nations conferences. IISD's Internet journal, */linkages/journal/*, is a bimonthly electronic multi-media subscription magazine focusing on global negotiations. Its reporting service, Sustainable Developments, reports on environmental and development negotiations for meetings and symposia via the Internet. IISD also operates IISDnet (http://iisd1.iisd.ca/), an Internet information site featuring research, new trends, global activities, contacts, information on IISD's activities and projects, including United Nations negotiations on environment and development, corporate environmental reporting, and information on trade issues.

IISD is the umbrella organization for Earth Council, an international **nongovernmental organization** (NGO) created in 1992 as a result of the **United Nations Earth Summit**. The organization creates measurements for achieving sustainable development and assesses practices and economic measures for their effects on sustainable development. Earth Council coordinated the Rio+5 Forum in Rio de Janeiro in March 1997, which assessed progress towards

sustainable development since the Earth Summit in 1992. IISD has produced two publications, *Trade and Sustainable Development* and *Guidelines for the Practical Assessment of Progress Toward Sustainable Development*.

International Joint Commission

The International Joint Commission (IJC) is a permanent, independent organization of the United States and Canada formed to resolve trans-boundary ecological concerns. Founded in 1912 as a result of provisions under the Boundary Waters Treaty of 1909, the IJC was patterned after an earlier organization, the Joint Commission, which was formed by the United States and Britain.

The IJC consists of six commissioners, with three appointed by the President of the United States, and three by the Governor-in-Council of Canada, plus support personnel. The commissioners and their organizations generally operate freed from direct influence or instruction from their national governments. The IJC is frequently cited as an excellent model for international dispute resolution because of its history of successfully and objectively dealing with **natural resources** and environmental disputes between friendly countries.

The major activities of the IJC have dealt with apportioning, developing, conserving, and protecting the binational **water resources** of the United States and Canada. Some other issues, including transboundary **air pollution**, have also been addressed by the Commission.

The power of the IJC comes from its authority to initiate scientific and socio-economic investigations, conduct quasi-judicial inquiries, and arbitrate disputes.

Of special concern to the IJC have been issues related to the **Great Lakes**. Since the early 1970s, IJC activities have been substantially guided by provisions under the 1972 and 1978 **Great Lakes Water Quality Agreement** plus updated protocols. For example, it is widely acknowledged, and well documented, that environmental quality and **ecosystem health** have been substantially degraded in the Great Lakes. In 1985, the **Water Quality** Board of the IJC recommended that states and provinces with Great Lakes boundaries make a collective commitment to address this communal problem, especially with respect to **pollution**. These governments agreed to develop and implement remedial action plans (RAPs) towards the restoration of **environmental health** within their political jurisdictions. Forty-three areas of concern have been identified on the basis of environmental pollution, and each of these will be the focus of a remedial action plan.

An important aspect of the design and intent of the overall program, and of the individual RAPs, will be developing a process of integrated **ecosystem management**. **Ecosystem** management involves systematic, comprehensive approaches toward the restoration and protection of environmental quality. The ecosystem approach involves consideration of interrelationships among land, air, and water, as well as those between the inorganic **environment** and the biota, including humans. The ecosystem approach would replace the separate, more linear approaches that have traditionally been used to manage environmental problems. These conventional attempts have included directed programs to deal with particular resources such as fisheries, migratory birds, **land use**, or point sources and area sources of toxic emissions. Although these non-integrated methods have been useful, they have been limited because they have failed to account for important inter-relationships among environmental management programs, and among components of the ecosystem.

International Primate Protection League

Founded in 1974 by Shirley McGreal, International Primate Protection League (IPPL) is a global **conservation** organization that works to protect nonhuman primates, especially monkeys and apes (**chimpanzees**, orangutans, **gibbons**, and gorillas).

IPPL has 30,000 members, branches in the United Kingdom, Germany, and **Australia**, and field representatives in 31 countries. Its advisory board consists of scientists, conservationists, and experts on primates, including the world-renowned primatologist **Jane Goodall**, whose famous studies and books are considered the authoritative texts on chimpanzees. Her studies have also heightened public interest and sympathy for chimpanzees and other nonhuman primates.

IPPL runs a sanctuary and **rehabilitation** center at its Summerville, South Carolina headquarters, which houses two dozen gibbons and other abandoned, injured, or traumatized primates who are refugees from medical laboratories or abusive pet owners. IPPL concentrates on investigating and fighting the multi-million dollar commercial trafficking in primates for medical laboratories, the **pet trade**, and zoos, much of which is illegal trade and smuggling of **endangered species** protected by international law. IPPL is considered the most active and effective group working to stem the cruel and often lethal trade in primates.

IPPL's work has helped to save the lives of literally tens of thousands of monkeys and apes, many of which are threatened or endangered **species**. For example, the group was instrumental in persuading the governments of India and Thailand to ban or restrict the export of monkeys, which were being shipped by the thousands to research laboratories and pet stores across the world.

The trade in primates is especially cruel and wasteful, since a common way of capturing them is by shooting the mother, which then enables poachers to capture the infant. Many captured monkeys and apes die enroute to their destinations, often being transported in sacks, crates, or hidden in other devices.

IPPL often undertakes actions and projects that are dangerous and require a good deal of skill. In 1992, its investigations have led to the conviction of a Miami, Florida, animal dealer for conspiring to help smuggle six baby orangutans captured in the jungles of Borneo. The endangered **orangutan** is protected by the Convention on International Trade in Endangered Species of **Fauna** and Flora (CITES), as well as by the United States **Endangered Species Act**. In retaliation, the dealer unsuccessfully sued McGreal, as did a multi-national corporation she once criticized for its plan to capture chimpanzees and use them for hepatitis research in Sierra Leone.

A more recent victory for IPPL occurred in April 2002. In 1997, Chicago O'Hare airport received two shipments from Indonesia, each of which contained more than 250 illegally imported monkeys. Included in the shipments were dozens of unweaned baby monkeys. After several years of pursuing the issue, the U.S. **Fish and Wildlife Service** and the U.S. Federal prosecutors charged the LABS Company (a breeder of monkeys for research based in the United States) and several of its employees, including its former president, on eight felonies and four misdemeanors.

IPPL publishes *IPPL News* several times a year and sends out periodic letters alerting members of events and issues that affect primates.

International Register of Potentially Toxic Chemicals (U. N. Environment Programme)

The International Register of Potentially Toxic **Chemicals** is published by the **United Nations Environment Programme** (UNEP). Part of UNEP's three-pronged **Earthwatch** program, the register is an international inventory of chemicals that threaten the **environment**. Along with the **Global Environment Monitoring System** and **INFOTERRA**, the register monitors and measures environmental problems worldwide. Information from the register is routinely shared with agencies in developing countries. **Third World** countries have long been the toxic dumping grounds for the world, and they still use many chemicals that have been banned elsewhere. Environmental groups regularly send information from the register to toxic chemical users in developing countries as part of their effort to stop the export of toxic **pollution**.

International Society for Environmental Ethics

The International Society for **Environmental Ethics** (ISEE) is an organization that seeks to educate people about the environmental ethics and philosophy concerning **nature**. An environmental ethic is the philosophy that humans have a moral duty to sustain the natural **environment** and attempts to answer how humans should treat other **species** (plant and animal), use Earth's **natural resources**, and place value on the aesthetic experiences of nature.

The society is an auxiliary organization of the American Philosophical Association, with about 700 members in over 20 countries. Many of ISEE's current members are philosophers, teachers, or environmentalists. The ISEE officers include president Mark Sagoff (Institute for Philosophy and Public Policy, University of Maryland) and John Baird Callicott, vice president, (professor of philosophy at the University of North Texas). Two other key members are editors

of the ISEE newsletter, Jack Weir and **Holmes Rolston**, III (Professor of Philosophy, Colorado State University). All have contributed to the ongoing ISEE Master Environmental Ethics Bibliography.

ISEE publishes a quarterly newsletter available to members in print form and maintains an Internet site of back issues. Of special note is the ISEE Bibliography, an ongoing project that contains over 5,000 records from journals such as *Environmental Ethics*, *Environmental Values*, and the *Journal of Agricultural and Environmental Ethics.*

Another work in progress, the ISEE Syllabus Project, continues to be developed by Callicott and Robert Hood, doctoral candidate at Bowling Green State University. They maintain a database of course offerings in environmental philosophy and ethics, based on information from two-year community colleges and four-year state universities, private institutions, and master's- and doctorate-granting universities. ISEE supports the enviroethics program which has spurred many Internet discussion groups and is constantly expanding into new areas of communication.

International trade in toxic waste

Just as VCRs, cars, and laundry soap are traded across borders, so too is the waste that accompanies their production. In the United States alone, industrial production accounts for at least 500 million lb (230 million kg) of **hazardous waste** a year. The industries of other developed nations also produce waste. While some of it is disposed within national borders, a portion is sent to other countries where costs are cheaper and regulations less stringent than in the waste's country of origin.

Unlike consumer products, internationally traded hazardous waste has begun to meet local opposition. In some recent high-profile cases, barges filled with waste have traveled the world looking for final resting places. In at least one case, a ship may have dumped about ten tons of toxic municipal incinerator ash in the ocean after being turned away from dozens of ports. In recent years national and international bodies have begun to voice official opposition to this dangerous trade through bans and regulations.

The international trade in toxic wastes is, at bottom, waste disposal with a foreign-relations twist. Typically a manufacturing facility generates waste during the production process. The facility manager pays a waste-hauling firm to dispose of the waste. If the landfills in the country of origin cost too much, or if there are no landfills that will take the waste, the disposal firm will find a cheaper option, perhaps a **landfill** in another country. In the United States, the shipper must then notify the **Environmental Protection Agency** (EPA), which then notifies the State Department. After ascertaining that the destination country will indeed accept the waste, American regulators approve the sale.

Disposing of the waste overseas in a landfill is only the most obvious example of this international trade. Waste haulers also sell their cargo as raw materials for **recycling**. For example, used lead-acid batteries discarded by American consumers are sent to Brazil where factory workers extract and resmelt the **lead**. Though the lead-acid alone would classify as hazardous, whole batteries do not. Waste haulers can ship these batteries overseas without notification to Mexico, Japan, and Canada, among other countries. In other cases, waste haulers sell products, like DDT, that have been banned in one country to buyers in another country that has no ban. Whatever the strategy for disposal, waste haulers are most commonly small, independent operators who provide a service to waste producers in industrialized countries.

These haulers bring waste to other countries to take advantage of cheaper disposal options and less stringent regulatory climates. Some countries forbid the disposal of the certain kinds of waste. Countries without such prohibitions will import more waste. Cheap landfills depend on cheap labor and land. Countries with an abundance of both can become attractive destinations. Entrepreneurs or government officials in countries, like Haiti, or regions within countries, such as Wales, that lack a strong manufacturing base, view waste disposal as a viable, inexpensive business. Inhabitants may view it as the best way to make money and create jobs. Simply by storing hazardous waste, the country of Guinea-Bissau could have made $120 million, more money than its annual budget.

Though the **less developed countries** (LDC) predictably receive large amounts of toxic waste, the bulk of the international trade occurs between industrialized nations. Canada and the United Kingdom in particular import large volumes of toxic waste. Canada imports almost 85% of the waste sent abroad by American firms, approximately 150,000 lb (70,000 kg) per year. The bulk of the waste ends up at an incinerator in Ontario or a landfill in Quebec. Because Canada's disposal regulations are less strict than United States laws, the operators of the landfill and incinerator can charge lower fees than similar disposal sites in the United States.

A waste hauler's life becomes complicated when the receiving country's government or local activists discover that

the waste may endanger health and the **environment**. Local regulators may step in and forbid the sale. This happened many times in the case of the *Khian Sea*, a ship that had contracted to dispose of Philadelphia's incinerator ash. The ship was turned away from Haiti, from Guinea-Bissau, from Panama, and from Sri Lanka. For two years, beginning in 1986, the ship carried the toxic ash from port to port looking for a home for its cargo before finally mysteriously losing the ash somewhere in the Indian Ocean.

This early **resistance** to toxic-waste dumping has since led to the negotiation of international treaties forbidding or regulating the trade in toxic waste. In 1989, the African, Caribbean, and Pacific countries (ACP) and the countries belonging to the European Economic Community (EEC) negotiated the Lome IV Convention, which bans shipments of nuclear and hazardous waste from the EEC to the ACP countries. ACP countries further agreed not to import such waste from non-EEC countries. Environmentalists have encouraged the EEC to broaden its commitment to limiting waste trade.

In the same year, under the auspices of the **United Nations Environment Programme** (UNEP), the **Basel Convention** on the Control of Transboundary Movements of Hazardous Wastes and Their Disposal was negotiated. This requires shippers to obtain government permission from the destination country before sending waste to foreign landfills or incinerators. Critics contend that Basel merely formalizes the trade.

In 1991, the nations of the Organization of African Unity negotiated another treaty restricting the international waste trade. The Bamako Convention on the Ban of the Import into Africa and the Control of Transboundary Movement and Management of Hazardous Wastes within Africa criminalized the import of all hazardous waste. Bamako further forbade waste traders from importing to Africa materials that had been banned in one country to a country that has no such ban. Bamako also radically redefined the assessment of what constitutes a health hazard. Under the treaty, all **chemicals** are considered hazardous until proven otherwise.

These international strategies find their echoes in national law. Less developed countries have tended to follow the Lome and Bamako examples. At least eighty-three African, Latin-Caribbean, and Asian-Pacific countries have banned hazardous waste imports. And the United States, in a policy similar to the Basel Convention, requires hazardous waste shipments to be authorized by the importing country's government.

The efforts to restrict toxic waste trade reflect, in part, a desire to curb environmental inequity. When waste flows from a richer country to a poorer country or region, the inhabitants living near the incinerator, landfill, or recycling facility are exposed to the dangers of toxic compounds. For example, tests of workers in the Brazilian lead resmelting operation found blood-lead levels several times the United States standard. Lead was also found in the water supply of a nearby farm after five cows died. The loose regulations that keep prices low and attract waste haulers mean that there are fewer safeguards for local health and the environment. For example, leachate from unlined landfills can contaminate local **groundwater**. Jobs in the disposal industry tend to be lower paying than jobs in manufacturing. The inhabitants of the receiving country receive the wastes of industrialization without the benefits.

Stopping the waste trade is a way to force manufacturers to change production processes. As long as cheap disposal options exist, there is little incentive to change. A waste-trade ban makes hazardous waste expensive to discard, and will force business to search for ways to reduce this cost.

Companies that want to reduce their hazardous waste may opt for source reduction, which limits the hazardous components in the production process. This can both reduce production costs and increase output. A Monsanto facility in Ohio saved more than $3 million dollars a year while eliminating more than 17 million lb (8 million kg) of waste. According to officials at the plant, average yield increased by 8%. Measures forced by a lack of disposal options can therefore benefit the corporate bottom line, while reducing risks to health and the environment. *See also* Environmental law; Environmental policy; Groundwater pollution; Hazardous waste siting; Incineration; Industrial waste treatment; Leaching; Ocean dumping; Radioactive waste; Radioactive waste management; Smelter; Solid waste; Solid waste incineration; Solid waste recycling and recovery; Solid waste volume reduction; Storage and transport of hazardous materials; Toxic substance; Waste management; Waste reduction

International Voluntary Standards

International Voluntary Standards are industry guidelines or agreements that provide technical specifications so that products, processes, and services can be used worldwide. The need for development of a set of international standards to be followed and used consistently for environmental management systems was recognized in response to an increased desire by the global community to improve environmental management practices. In the early 1990s, the International Organization for Standardization or ISO, which is located in Geneva, Switzerland, began development of a strategic plan to promote a common international approach to environmental management. ISO 14000 is the title of a series of voluntary international environmental standards that is under development by ISO and is 142 member nations, including the United States. Some of the standards developed by ISO include standardized sampling, testing and analytical methods for use in the monitoring of environmental variables such as the quality of air, water and **soil**.

[*Marie H. Bundy*]

International Whaling Commission

see **International Convention for the Regulation of Whaling (1946)**

International Wildlife Coalition

The International **Wildlife** Coalition (IWC) was established by a small group of individuals who came from a variety of environmental and **animal rights** organizations in 1984. Like many NGOs (nongovernmental organizations) that arose in the 1970s and 1980s their initial work involved the protection of **whales**. The IWC raised money for whale **conservation** programs on endangered Atlantic humpback whale populations. This was one of the first **species** where researchers identified individual animals through tail photographs. Using this technique the IWC developed what is now a common tool, a whale adoption program based on individual animals with human names.

From that basis, the fledgling group established itself in an advocacy role with three principles in their mandate: to prevent cruelty to wildlife, to prevent killing of wildlife, and to prevent destruction of wildlife **habitat**. In light of those principles, the IWC can be characterized as an extended animal rights organization. They maintain the "prevention of cruelty" aspect common to humane societies, perhaps the oldest progenitor of animal rights groups. In standing by an ethic of preventing killing, they stand with animal rights groups, but by protecting habitat they take a more significant step by acting in a broad way to achieve their initial two principles.

The program thus works at both ends of the spectrum, undertaking **wildlife rehabilitation** and other programs dealing with the individual animals, as well as lobbying and promoting letter writing campaigns to improve wildlife legislation. For example, they have used their Brazilian office to create pressure to combat the international trade in exotic pets, and their Canadian office to oppose the harp seal hunt and the deterioration of Canada's impending **endangered species** legislation. Their United States-based operation has built a reputation in the research field working with government agencies to ensure that whale-watching on the eastern seaboard does not harm the whales. Offices in the United Kingdom are a focus for the IWC concern over the European Community policies, such as lifting their ban on importing fur from animals killed in leg hold traps.

It has become evident that the diversity within the varied groups that constitute the environmental community is a positive force, however, most conservation NGOs do not cross the gulf between animal rights and habitat conservation. A clear distinction exists between single animal approaches and broader conservation ideals, as they appeal to different protection strategies, and potentially different donors. Although the emotional appeal of releasing porpoises from fishing nets alive outranks backroom lobbying for changes in fishing regulations, the lobbying effort protect more porpoises. The IWC may be deemed more successful by exploiting a range of targets, or less so than a dedicated advocacy group applying all its focus to one issue. They can point to a growth from a modest 3,000 supporters in the beginning, to over 100,000 people supporting the International Wildlife Coalition today.

[*David Duffus*]

Intrinsic value

Saying that an object has intrinsic value means that, even though it has no specific use, market, or monetary value, it

nevertheless can be valuable in and of itself and for its own sake. The **Northern spotted owl** (*Strix occidentalis caurina*) for example, has no instrumental or market value; it is not a means to any human end, nor is it sold or traded in any market. But, environmentalists argue, utility and price are not the only measures of worth. Indeed, they say, some of the things humans value most—truth, love, respect—are not for sale at any price, and to try to put a price on them would only tend to cheapen them. Such things have "intrinsic value."

Similarly, environmentalists say, the natural **environment** and its myriad life-forms are valuable in their own right. **Wilderness**, for instance, has intrinsic value and is worthy of protecting for its own sake. To say that something has intrinsic value is not necessarily to deny that it may also have instrumental value for humans and non-human animals alike. Deer, for example, have intrinsic value; but they also have instrumental value as a food source for **wolves** and other predator **species**. *See also* Shadow pricing

Introduced species

Introduced **species** (also called invasive species) are those that have been released by humans into an area to which they are not native. These releases can occur accidently, from places such as the cargo holds of ships. They can also occur intentionally, and species have been introduced for a range of ornamental and recreational uses, as well as for agricultural, medicinal, and **pest** control purposes.

Introduced species can have dramatically unpredictable effects on the **environment** and native species. Such effects can include overabundance of the introduced species, competitive displacement, and disease-caused **mortality** of the native species. Numerous examples of adverse consequences associated with the accidental release of species or the long term effects of deliberately introduced species exist in the United States and around the world. Introduced species can be beneficial as long as they are carefully regulated. Almost all the major varieties of grain and vegetables used in the United States originated in other parts of the world. This includes corn, rice, wheat, tomatoes, and potatoes.

The **kudzu** vine, which is native to Japan, was deliberately introduced into the southern United States for **erosion** control and to shade and feed livestock. It is, however, an extremely aggressive and fast-growing species, and it can form continuous blankets of foliage that cover forested hillsides, resulting in malformed and dead trees. Other species introduced as ornamentals have spread into the wild, displacing or outcompeting native species. Several varieties of cultivated roses, such as the multiflora rose, are serious pests and nuisance shrubs in field and pastures. The **purple loosestrife**, with its beautiful purple flowers, was originally brought from Europe as a garden ornamental. It has spread rapidly in freshwater **wetlands** in the northern United States, displacing other plants such as cattails. This is viewed with concern by ecologists and **wildlife** biologists since the food value of loosestrife is minimal, while the roots and starchy tubes of cattails are an important food source to muskrats. Common ragweed was accidently introduced to North America, and it is now a major health irritant for many people.

Introduced species are sometimes so successful because human activity has changed the conditions of a particular environment. The Pine Barrens of southern New Jersey form an **ecosystem** that is naturally acidic and low in nutrients. Bogs in this area support a number of slow-growing plant species that are adapted to these conditions, including peat moss, sundews, and pitcher plants. But **urban runoff**, which contain fertilizers, and **wastewater effluent**, which is high in both **nitrogen** and **phosphorus**, have enriched the bogs; the waters there have become less acidic and shown a gradual elevation in the concentration of nutrients. These changes in **aquatic chemistry** have resulted in changes in plant species, and the acidophilus mosses and herbs are being replaced by fast-growing plants that are not native to the Pine Barrens.

Zebra mussels were transported by accident from Europe to the United States, and they are causing severe problems in the **Great Lakes**. They proliferate at a prodigious rate, crowding out native species and clogging industrial and municipal water-intake pipes. Many ecologists fear that shipping traffic will transport the **zebra mussel** to harbors all over the country. Scattered observations of this tiny crustacean have already been made in the lower **Hudson River** in New York.

Although introduced species are usually regarded with concern, they can occasionally be used to some benefit. The **water hyacinth** is an aquatic plant of tropical origin that has become a serious clogging nuisance in lakes, streams, and waterways in the southern United States. Numerous methods of physical and chemical removal have been attempted to eradicate or control it, but research has also established that the plant can improve **water quality**. The water hyacinth has proved useful in the withdrawal of nutrients from sewage and other wastewater. Many constructed wetlands, polishing ponds, and waste lagoons in waste treatment plants now take advantage of this fact by routing wastewater through floating beds of water hyacinth.

The reintroduction of native species is extremely difficult, and it is an endeavor that has had low rates of success. Efforts by the **Fish and Wildlife Service** to reintroduce the endangered **whooping crane** into native **habitat** in the southwestern United States were initially unsuccessful be-

cause of the fragility of the eggs, as well as the poor parenting skills of birds raised in captivity. The service then devised a strategy of allowing the more common sandhill crane to incubate the eggs of captive whooping cranes in **wilderness** nests, and the fledglings were then taught survival skills by their surrogate parents. Such projects, however, are extremely time and labor intensive; they are also costly and difficult to implement for large numbers of most species.

Due to the difficulties and expense required to protect native species and to eradicate introduced species, there are not many international laws and policies that seek to prevent these problems before they begin. Thus customs agents at ports and airports routinely check luggage and cargo for live plant and animal materials to prevent the accidental or deliberate transport of non-native species. Quarantine policies are also designed to reduce the **probability** of spreading introduced species, particularly diseases, from one country to another.

There are similar concerns about genetically engineered organisms, and many have argued that their creation and release could have the same devastating environmental consequences as some introduced species. For this reason, the use of bioengineered organisms is highly regulated; both the **Food and Drug Administration** and the **Environmental Protection Agency** (EPA) impose strict controls on the field testing of bioengineered products, as well as on their cultivation and use.

Conservation policies for the protection of native species are now focused on habitats and ecosystems rather than single species. It is easier to prevent the encroachment of introduced species by protecting an entire ecosystem from disturbance, and this is increasingly well recognized both inside and outside the conservation community. *See also* Bioremediation; Endangered species; Fire ants; Gypsy moth; Rabbits in Australia; Wildlife management

Iodine 131

A radioactive **isotope** of the element iodine. During the 1950s and early 1960s, iodine-131 was considered a major health hazard to humans. Along with cesium-137 and strontium-90, it was one of the three most abundant isotopes found in the fallout from the atmospheric testing of **nuclear weapons**. These three isotopes settled to the earth's surface and were ingested by cows, ultimately affecting humans by way of dairy products. In the human body, iodine-131, like all forms of that element, tends to concentrate in the thyroid, where it may cause **cancer** and other health disorders. The Chernobyl nuclear reactor explosion is known to have released large quantities of iodine-131 into the **atmosphere**. *See also* Radioactivity

Ion

Forms of ordinary chemical elements that have gained or lost electrons from their orbit around the atomic nucleus and, thus, have become electrically charged. Positive ions (those that have lost electrons) are called *cations* because when charged electrodes are placed in a solution containing ions the positive ions migrate to the cathode (negative electrode). Negative ions (those that have gained extra electrons) are called *anions* because they migrate toward the anode (positive electrode). Environmentally important cations include the **hydrogen** ion (H^+) and dissolved metals. Important anions include the hydroxyl ion (OH^-) as well as many of the dissolved ions of nonmetallic elements. *See also* Ion exchange; Ionizing radiation

Ion exchange

The process of replacing one **ion** that is attached to a charged surface with another. A very important type of ion exchange is the exchange of cations bound to **soil** particles. Soil **clay minerals** and organic matter both have negative surface charges that bind cations. In a fertile soil the predominant exchangeable cations are Ca^{2+}, Mg^{2+} and K^+. In **acid** soils Al^{3+} and H^+ are also important exchangeable ions. When materials containing cations are added to soil, cations **leaching** through the soil are retarded by cation exchange.

Ionizing radiation

High-energy radiation with penetrating competence such as x rays and gamma rays which induces ionization in living material. Molecules are bound together with covalent bonds, and generally an even number of electrons binds the atoms together. However, high-energy penetrating radiation can

fragment molecules resulting in atoms with unpaired electrons known as "free radicals." The ionized "free radicals" are exceptionally reactive, and their interaction with the macromolecules (DNA, RNA, and proteins) of living cells can, with high dosage, lead to cell death. Cell damage (or death) is a function of penetration ability, the kind of cell exposed, the length of exposure, and the total dose of ionizing radiation. Cells that are mitotically active and have a high oxygen content are most vulnerable to ionizing radiation. *See also* Radiation exposure; Radiation sickness; Radioactivity

Iron minerals

The oxides and hydroxides of ferric iron (Fe(III)) are very important minerals in many soils, and are important suspended solids in some fresh water systems. Important oxides and hydroxides of iron include goethite, hematite, lepidocrocite, and ferrihydrite.

These minerals tend to be very finely divided and can be found in the clay-sized fraction of soils, and like other clay-sized minerals, are important adsorbers of ions. At high **pH** they adsorb hydroxide (OH^-) ions creating negatively charged surfaces that contribute to cation exchange surfaces. At low pH they adsorb **hydrogen** (H^+) ions, creating anion exchange surfaces. In the pH range between 8 and 9 the surfaces have little or no charge. Iron hydroxide and oxide surfaces strongly adsorb some environmentally important anions, such as phosphate, arsenate and selanite, and cations like **copper**, **lead**, manganese and chromium. These ions are not exchangeable, and in environments where iron oxides and hydroxides are abundant, surface **adsorption** can control the mobility of these strongly adsorbed ions.

The hydroxides and oxides of iron are found in the greatest abundance in older highly weathered landscapes. These minerals are very insoluble and during **soil weathering** they form from the iron that is released from the structure of the soil-forming minerals. Thus, iron oxide and hydroxide minerals tend to be most abundant in old landscapes that have not been affected by **glaciation**, and in landscapes where the rainfall is high and the rate of soil mineral weathering is high. These minerals give the characteristic red (hematite or ferrihydrite) or yellow-brown (goethite) colors to soils that are common in the tropics and subtropics. *See also* Arsenic; Erosion; Ion exchange; Phosphorus; Soil profile; Soil texture

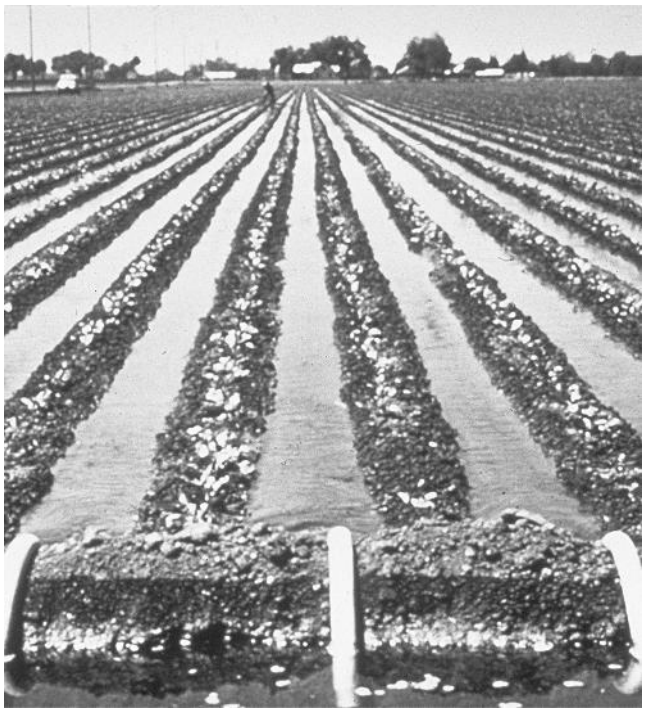
Irradiation of food

see **Food irradiation**

Irrigation

Irrigation is the method of supplying water to land to support plant growth. This technology has had a powerful role in the history of civilization. In **arid** regions sunshine is plentiful and **soil** is usually fertile, so irrigation supplies the critical factor needed for plant growth. Yields have been high, but not without costs. Historic problems include **salinization** and water **logging**; contemporary difficulties include immense costs, spread of water-borne diseases, and degraded aquatic environments.

One geographer described California's Sierra Nevada as the "mother nurse of the San Joaquin Valley." Its heavy winter snowpack provides abundant and extended **runoff** for the rich valley soils below. Numerous irrigation districts, formed to build diversion and storage **dams**, supply water through gravity-fed canals. The snow melt is low in nutrients, so salinization problems are minimal. Wealth from the lush fruit orchards has enriched the state.



By contrast, the **Colorado River**, like the Nile, flows mainly through arid lands. Deeply incised in places, the river is also limited for irrigation by the high salt content of **desert** tributaries. Still, demand for water exceeds supply. Water crossing the border into Mexico is so saline that the federal government has built a **desalinization** plant at Yuma, Arizona. Colorado River water is imperative to the Imperial Valley, which specializes in winter produce in the rich, delta soils. To reduce salinization problems, one-fifth of the water used must be drained off into the growing Salton Sea.

Salinization and water logging have long plagued the Tigris, Euphrates, and Indus River flood plains. Once fertile areas of Iraq and Pakistan are covered with salt crystals. Half of the irrigated land in our western states is threatened by salt buildup.

Some of the worst problems are degraded aquatic environments. The **Aswan High Dam** in Egypt has greatly amplified surface evaporation, reduced nutrients to the land and to fisheries in the delta, and has contributed to the spread of **schistosomiasis** via water snails in irrigation ditches. Diversion of **drainage** away from the **Aral Sea** for cotton irrigation has severely lowered the shoreline, and threatens this water body with ecological disaster.

Spray irrigation in the High Plains is lowering the Ogallala Aquifer's **water table**, raising pumping costs. Kesterson Marsh in the San Joaquin Valley has become a hazard to **wildlife** because of selenium **poisoning** from irrigation drainage. The federal **Bureau of Reclamation** has invested huge sums in dams and reservoirs in western states. Some question the wisdom of such investments, given the past century of farm surpluses, and argue that water users are not paying the true cost.

A farm irrigation system. (U. S. Geological Survey Reproduced by permission.)

Irrigation still offers great potential, but only if used with wisdom and understanding. New technologies may yet contribute to the world's ever-increasing need for food. *See also* Climate; Commercial fishing; Reclamation

Island biogeography

Island **biogeography** is the study of past and present animal and plant distribution patterns on islands and the processes that created those distribution patterns. Historically, island biogeographers mainly studied geographic islands—continental islands close to shore in shallow water and oceanic islands of the deep sea. In the last several decades, however, the study and principles of island biogeography have been extended to ecological islands such as forests and **prairie** fragments isolated by human development. Biogeographic "islands" may also include ecosystems isolated on mountaintops and landlocked bodies of water such as Lake Malawi in the African Rift Valley. Geographic islands, however, remain the main laboratories for developing and testing the theories and methods of island biogeography.

Equilibrium theory

Until the 1960s, biogeographers thought of islands as living museums—relict (persistent remnant of an otherwise extinct **species** of plant or animal) scraps of mainland ecosystems in which little changed—or closed systems mainly driven by **evolution**. That view began to radically change in 1967 when Robert H. MacArthur and Edward O. Wilson published *The Theory of Island Biogeography*.

In their book, MacArthur and Wilson detail the equilibrium theory of island biogeography—a theory that became the new paradigm of the field. The authors proposed that island ecosystems exist in dynamic equilibrium, with a steady turnover of species. Larger islands—as well as islands closest to a source of immigrants—accommodate the most species in the equilibrium condition, according to their theory. MacArthur and Wilson also worked out mathematical models to demonstrate and predict how island area and isolation dictate the number of species that exist in equilibrium.

Dispersion

The driving force behind species distribution is dispersion—the means by which plants and animals actively leave or are passively transported from their source area. An island **ecosystem** can have more than one source of colonization, but nearer sources dominate. How readily plants or animals disperse is one of the main reasons equilibrium will vary from species to species.

Birds and **bats** are obvious candidates for anemochory (dispersal by air), but some species normally not associated with flight are also thought to reach islands during storms or even normal wind currents. Orchids, for example, have hollow seeds that remain airborne for hundreds of kilometers. Some small spiders, along with other insects like bark lice, aphids, and ants (collectively knows as aerial **plankton**) often are among the first pioneers of newly formed islands.

Whether actively swimming or passively floating on logs or other debris, dispersal by sea is called thallasochory. **Crocodiles** have been found on Pacific islands 600 miles (950 km) from their source areas, but most amphibians, larger terrestrial reptiles, and, in particular, mammals, have difficulty crossing even narrow bodies of water. Thus, thalla-

sochory is the medium of dispersal primarily for fish, plants, and insects. Only small vertebrates such as lizards and snakes are thought to arrive at islands by sea on a regular basis.

Zoochory is transport either on or inside an animal. This method is primarily a means of plant dispersal, mostly by birds. Seeds ride along either stuck to feathers or survive passage through a bird's digestive tract and are deposited in new territory.

Anthropochory is dispersal by human beings. Although humans intentionally introduce domestic animals to islands, they also bring unintended invaders, such as rats.

Getting to islands is just the first step, however. Plants and animals often arrive to find harsh and alien conditions. They may not find suitable habitats. Food chains they depend on might be missing. Even if they manage to gain a foothold, their limited numbers make them more susceptible to **extinction**. Chances of success are better for highly adaptable species and those that are widely distributed beyond the island. Wide distribution increases the likelihood a species on the verge of extinction may be saved by the rescue effect, the replenishing of a declining population by another wave of immigration.

Challenging established theories

Many biogeographers point out that isolated ecosystems are more than just collections of species that can make it to islands and survive the conditions they encounter there. Several other contemporary theories of island biogeography build on MacArthur and Wilson's theory; other theories contradict it.

Equilibrium theory suggests that species turnover is constant and regular. Evidence collected so far indicates MacArthur and Wilson's model works well in describing communities of rapid dispersers who have a regular turnover, such as insects, birds, and fish. However, this model may not apply to species who disperse more slowly.

Proponents of historical legacy models argue that communities of larger animals and plants (forest trees, for example) take so long to colonize islands that changes in their populations probably reflect sudden climactic or geological upheaval rather than a steady turnover. Other theories suggest that equilibrium may not be dynamic, that there is little or no turnover. Through **competition**, established species keep out new colonists; the newcomers might occupy the same ecological niches as their predecessors. Established species may also evolve and adapt to close off those niches. Island resources and habitats may also be distinct enough to limit immigration to only a few well-adapted species.

Thus, in these later models, dispersal and colonization are not nearly as random as in MacArthur and Wilson's model. These less random, more deterministic theories of island ecosystems conform to specific assembly rules—a complex list of factors accounting for the species present in the source areas, the niches available on islands, and competition between species.

Some biogeographers suggest that every island—and perhaps every **habitat** on an island—may require its own unique model. Human disruption of island ecosystems further clouds the theoretical picture. Not only are habitats permanently altered or lost by human intrusion, but anthropochory also reduces an island's isolation. Thus, finding relatively undisturbed islands to test different theories can be difficult.

Since the time of naturalists Charles Darwin and his colleague, Alfred Wallace, islands have been ideal "natural laboratories" for studying evolution. Patterns of evolution stand out on islands for two reasons: island ecosystems tend to be simpler than other geographical regions, and they contain greater numbers of **endemic species**, plant, and animal species occurring only in a particular location.

Many island endemics are the result of adaptive radiation—the evolution of new species from a single lineage for the purpose of filling unoccupied ecological niches. Many species from mainland source areas simply never make it to islands, so species that can immigrate find empty ecological niches where once they faced competition. For example, monitor lizards immigrating to several small islands in Indonesia found the **niche** for large predators empty. Monitors on these islands evolved into Komodo Dragons, filling the niche.

Conservation of biodiversity

Theories of island biogeography also have potential applications in the field of **conservation**. Many conservationists argue that as human activity such as **logging** and ranching encroach on wild lands, remaining parks and reserves begin to resemble small, isolated islands. According to equilibrium theory, as those patches of wild land grow smaller, they support fewer species of plants and animals. Some conservationists fear that plant and animal populations in those parks and reserves will sink below minimum viable population levels—the smallest number of individuals necessary to allow the species to continue reproducing. These conservationists suggest that one way to bolster populations is to set aside larger areas and to limit species isolation by connecting parks and preserves with **wildlife** corridors.

Islands with greatest variety of habitats support the most species; diverse habitats promotes successful dispersal, survival, and reproduction. Thus, in attempting to preserve island **biodiversity**, conservationists focus on several factors: the size (the larger the island, the more habitats it contains), **climate**, geology (**soil** that promotes or restricts habitats), and age of the island (sparse or rich habitats). All of these factors must be addressed to ensure island biodiversity.

ISO 14000: International Environmental Management Standards

ISO 14000 refers to a series of environmental management standards that were adopted by the International Organization for Standardization (ISO) in 1996 and are beginning to be implemented by businesses across the world. Any person or organization interested in the **environment** and in the goal of improving environmental performance of businesses should be interested in ISO 14000. Such interested parties include businesses themselves, their legal representatives, environmental organizations and their members, government officials, and others.

What is the ISO and what are ISO standards?

The International Organization for Standardization (ISO) is a private (nongovernmental) worldwide organization whose purpose is to promote uniform standards in international trade. Its members are elected representatives from national standards organizations in 111 countries. The ISO covers all fields involving promoting goods, services, or products and where a Member Body suggests that standardization is desirable, with the exception of electrical and electronic engineering, which are covered by a different organization called the International Electrotechnical Commission (IEC). However, the ISO and the IEC work closely together.

Since the ISO began operations in 1947, its Central Secretariat has been located in Geneva, Switzerland. Between 1951 (when it published its first standard) and 1997, the ISO issued over 8,800 standards. Standards are documents containing technical specifications, rules, guidelines, and definitions to ensure equipment, products, and services perform as specified.

Among the best known standards published by the ISO are those that comprise the ISO 9000 series, which was developed between 1979–1986, and published in 1987. Because ISO 9000 is a forerunner to ISO 14000, it is important to understand the basic structure and function of ISO 9000. The ISO 9000 series is a set of standards for quality management and quality assurance. The standards apply to processes and systems that produce products; they do not apply to the products themselves. Further, the standards provide a general framework for any industry; they are not industry-specific. A company that has become registered under ISO 9000 has demonstrated that it has a documented system for quality that is in place and consistently applied. ISO 9000 standards apply to all kinds of companies whether large or small, in services or manufacturing.

The latest major set of standards published by the ISO is the ISO 14000 series. The impetus for that series came from the United Nations Conference on the Environment and Development (UNCED), which was held in Rio De Janeiro in 1992 and attended by representatives of over one hundred nations. One of the documents resulting from that conference was the *Global Environmental Initiative*, which prompted the ISO to develop its ISO 14000 series of international environmental standards. The ISO's goal is to insure that businesses adopt common internal procedures for environmental controls including, but not limited to, audits. It is important to note that the standards are process standards, not performance standards. The goal is to ensure that businesses are in compliance with their own national and local applicable environmental laws and regulations. The initial standards in the series include numbers 14001, 14004, and 14010-14012; all of them adopted by the ISO in 1996.

Provisions of ISO 14000 Series standards

ISO 14000 sets up criteria pursuant to which a company may become registered or certified as to its environmental management practices.

Central to the process of registration pursuant to ISO 14000 is a company's Environmental Management System (EMS). The EMS is a set of procedures for assessing compliance with environmental laws and company procedures for environmental protection, identifying and resolving with problems, and engaging the company's workforce in a commitment to improved environmental performance by the company.

ISO 14001 series can be divided into two groups: guidance documents and specification documents. The series sets out standards against which a company's EMS will be evaluated. For example, it must include an accurate summary of the legal standards with which the company must comply,

such as permit stipulations, and relevant provisions of statutes and regulations, and even provisions of administrative or court-certified consent judgments. To become certified, the EMS must: (1) include an **environmental policy**; (2) establish plans to meet environmental goals and comply with legal requirements; (3) provide for implementation of the policy and operation under it including training for personnel, communication, and document control; (4) set up monitoring and measurement devices and an audit procedure to insure continuing improvement; and (5) provide for management review. The EMS must be certified by a registrar who has been qualified under ISO 13012, a standard that predates the ISO 14000 series.

The ISO 14004 series is a guidance document that gives advice that may be followed but is not required. It includes five principles each of which corresponds to one of the five areas of ISO 14001 listed above.

ISO 14010, 14011, and 14012 are auditing standards. For example, 14010 covers general principles of **environmental auditing**, and 14011 provides guidelines for auditing of an Environmental Management System (EMS). ISO 14012 provides guidelines for establishing qualifications for environmental auditors, whether those auditors are internal or external.

Plans for additional standards within the ISO 14000 Series standards

The ISO is considering proposals for standards on training and certifying independent auditors (called registrars) who will certify that ISO 14000-certified business have established and adhere to stringent internal systems to monitor and improve their own environmental protection actions. Later the ISO may also establish standards for assessing a company's environmental performance. Standards may be adopted to for use of eco-labeling and **life cycle assessment** of goods involved in international trade.

Benefits and consequences of ISO 14000 Series standards

A company contemplating obtaining ISO 14000 registration must evaluate its potential advantages as well as its costs to the company.

ISO 14000 certification may bring various rewards to companies. For example, many firms are hoping that, in return for obtaining ISO 14000 certification (and the actions required to do so), regulatory agencies such as the U.S. **Environmental Protection Agency** (EPA) will give them more favorable treatment. For example, leniency might be shown in less stringent filing or monitoring requirements or even less severe sanctions for past or present violations of environmental statutes and regulations.

Further, compliance may be merely for good public relations, leading consumers to view the certified company as a good corporate citizen that works to protect the environment. There is public pressure on companies to demonstrate their environmental stewardship and accountability; obtaining ISO 14000 certification is one way to do so.

The costs to the company will depend on the scope of the Environmental Management System (EMS). For example, the EMS might be international, national, or limited to individual plants operated by the company. That decision will affect the costs of the environmental audit considerably. National and international systems may prove to be costly.

On the other hand, a company may realize cost savings. For example, an insurance company may give reduced rates on insurance to cover accidental **pollution** releases to a company that has a proven environmental management system in place. Internally, by implementing an EMS, a company may realize cost savings as a result of **waste reduction**, use of less fewer toxic **chemicals**, less energy use, and **recycling**.

A major legal concern raised by lawyers studying the ISO 14000 standards relates to the question of confidentiality. There are serious questions as to whether a governmental regulatory agency can require disclosure of information discovered during a self-audit by a company. The use of a third-party auditor during preparation of the EMS process may weaken a company's argument that information discovered is privileged.

ISO 14000 has potential consequences with respect to international law as well as international trade. ISO 14000 is intended to promote a series of universally accepted EMS practices and lead to consistency in environmental standards between and among trading partners. Some developing countries such as Mexico are reviewing ISO 14000 standards and considering incorporating their provisions within their own environmental laws and regulations. On the other hand, some developing countries have suggested that environmental standards created by ISO 14000 may constitute nontariff barriers to trade in that costs of ISO 14000 registration may be prohibitively high for small- to medium-size companies.

Companies that have implemented ISO 9000 have learned to view their companies' operations through a "quality of management" lens and implementation of ISO 14000 may lead to use of "environmental quality" lens. ISO 14000 has the potential to lead to two kinds of cultural changes. First, within the corporation, it has the potential to lead to consideration of environmental issues throughout the company and its business decisions ranging from hiring of employees to marketing. Second, ISO 14000 has the potential to become part of a global culture as the public comes to view ISO 14000 certification as a benchmark connoting good environmental stewardship by a company.

Isotope

Different forms of atoms of the same element. Atoms consist of a nucleus, containing positively-charged particles (protons) and neutral particles (neutrons), surrounded by negatively-charged particles (electrons). Isotopes of an element differ only in the number of neutrons in the nucleus and hence in atomic weight. The nuclei of some isotopes are unstable and undergo **radioactive decay**. An element can have several stable and radioactive isotopes, but most elements have only two or three isotopes that are of any importance. Also, for most elements the radioactive isotopes are only of concern in material exposed to certain types of radiation sources. **Carbon** has three important isotopes with atomic weights of 12, 13, and 14. C-12 is stable and represents 98.9% of natural carbon. C-13 is also stable and represents 1.1% of natural carbon. C-14 represents an insignificant fraction of naturally-occurring carbon, but it is radioactive and important because its radioactive decay is valuable in the dating of fossils and ancient artifacts. It is also useful in tracing the reactions of carbon compounds in research. *See also* Nuclear fission; Nuclear power; Radioactivity; Radiocarbon dating

Itai-itai disease

The symptoms of Itai-Itai disease were first observed in 1913 and characterized between 1947 and 1955; it was 1968, however, before the Japanese Ministry of Health and Welfare officially declared that the disease was caused by chronic **cadmium poisoning** in conjunction with other factors such as the stresses of pregnancy and lactation, aging, and dietary deficiencies of vitamin D and calcium. The name arose from the cries of pain, "itai-itai" (ouch-ouch) by the most seriously stricken victims, older Japanese farm women. Although men, young women, and children were also exposed, 95% of the victims were post-menopausal women over 50 years of age. They usually had given birth to several children and had lived more than 30 years within 2 mi (3 km) of the lower stream of the Jinzu River near Toyama.

The disease started with symptoms similar to rheumatism, neuralgia, or neuritis. Then came bone lesions, osteomalacia, and osteoporosis, along with renal disfunction and proteinuria. As it escalated, pain in the pelvic region caused the victims to walk with a duck-like gait. Next, they were incapable of rising from their beds because even a slight strain caused bone fractures. The suffering could last many years before it finally ended with death. Overall, an estimated 199 victims have been identified, of which 162 had died by December 1992.

The number of victims increased during and after World War II as production expanded at the Kamioka Mine owned by the Mitsui Mining and Smelting Company. As 3,000 tons of zinc-lead ore per day were mined and smelted, cadmium was discharged in the **wastewater**. Downstream, farmers withdrew the fine particles of **flotation tailings** in the Jinzu River along with water for drinking and crop **irrigation**. As rice plants were damaged near the irrigation inlets, farmers dug small **sedimentation** pools that were ineffective against the nearly invisible poison.

Both the numbers of Itai-Itai disease patients and the damage to the rice crops rapidly decreased after the mining company built a large settling basin to purify the wastewater in 1955. However, even after the **discharge** into the Jinzu River was halted, the cadmium already in the rice paddy soils was augmented by airborne exhausts. Mining operations in several other Japanese prefectures also produced cadmium-contaminating rice, but afflicted individuals were not certified as Itai-Itai patients. That designation was applied only to those who lived in the Jinzu River area.

In 1972 the survivors and their families became the first **pollution** victims in Japan to win a lawsuit against a major company. They won because in 1939 Article 109 of the Mining Act had imposed strict liability upon mining facilities for damages caused by their activities. The plaintiffs had only to prove that cadmium discharged from the mine caused their disease, not that the company was negligent. As epidemiological proof of causation sufficed as legal proof in this case, it set a precedent for other pollution litigation as well.

Despite legal success and compensation, the problem of contaminated rice continues. In 1969 the government initially set a maximum allowable standard of 0.4 **parts per million** (ppm) cadmium in unpolished rice. However, because much of the contaminated farmland produced grain in excess of that level, in 1970 under the Foodstuffs Hygiene Law this was raised to 1 ppm cadmium for unpolished rice and 0.9 ppm cadmium for polished rice. To restore contaminated farmland, Japanese authorities instituted a program in which, each year, the most highly contaminated soils in a small area are exchanged for uncontaminated soils. Less contaminated soils are rehabilitated through the addi-

tion of lime, phosphate, and a cadmium sequestering agent, EDTA.

By 1990 about 10,720 acres (4,340 ha), or 66.7% of the approximately 16,080 acres (6,510 ha) of the most highly cadmium contaminated farmland had been restored. In the remaining contaminated areas where farm families continue to eat homegrown rice, the symptoms are alleviated by treatment with massive doses of vitamins B1, B12, D, calcium, and various hormones. New methods have also been devised to cause the cadmium to be excreted more rapidly. In addition, the high costs of compensation and restoration are leading to the conclusion that prevention is not only better but cheaper. This is perhaps the most encouraging factor of all. *See also* Bioaccumulation; Environmental law; Heavy metals and heavy metal poisoning; Mine spoil waste; Smelter; Water pollution

IUCN—The World Conservation Union

Founded in 1948 as the International Union for the Conservation of Nature and Natural Resources (IUCN), IUCN works with governments, conservation organizations, and industry groups to conserve **wildlife** and approach the world's environmental problems using "sound scientific insight and the best available information." Its membership, currently over 980, comes from 140 countries and includes 56 sovereign states, as well as government agencies and nongovernmental organizations. IUCN exists to serve its members, representing their views and providing them with the support necessary to achieve their goals. Above all, IUCN works with its members "to achieve development that is sustainable and that provides a lasting improvement in the quality of life for people all over the world." IUCN's three basic conservation objectives are: (1) to secure the conservation of nature, and especially of biological diversity, as an essential foundation for the future; (2) to ensure that where the earth's natural resources are used this is done in a wise, equitable, and sustainable way; (3) to guide the development of human communities toward ways of life that are both of good quality and in enduring harmony with other components of the **biosphere**.

IUCN is one of the few organizations to include both governmental agencies and nongovernmental organizations. It is in a unique position to provide a neutral forum where these organizations can meet, exchange ideas, and build partnerships to carry out conservation projects. IUCN is also unusual in that it both develops environmental policies and then implements them through the projects it sponsors. Because the IUCN works closely with, and its membership includes, many government scientists and officials, the organization often takes a conservative, pro-management, as opposed to a "preservationist," approach to wildlife issues. It may encourage or endorse limited **hunting** and commercial exploitation of wildlife if it believes this can be carried out on a sustainable basis.

IUCN maintains a global network of over 5,000 scientists and wildlife professionals who are organized into six standing commissions that deal with various aspects of the union's work. There are commissions on Ecology, Education, Environmental Planning, **Environmental Law**, National Parks and Protected Areas, and **Species** Survival. These commissions create action plans, develop policies, advise on projects and programs, and contribute to IUCN publications, all on an unpaid, voluntary basis.

IUCN publishes an authoritative series of "Red Data Books," describing the status of rare and endangered wildlife. Each volume provides information on the population, distribution, **habitat** and ecology, threats, and protective measures in effect for listed species. The "Red Data Books" concept was originated in the mid-1960s by the famous British conservationist Sir Peter Scott, and the series now includes a variety of publication on regions and species. Other titles in the series of "Red Data Books" include *Dolphins, Porpoises, and Whales of the World*; *Lemurs of Madagascar and the Comoros*; *Threatened Primates of Africa*; *Threatened Swallowtail Butterflies of the World*; *Threatened Birds of the Americas*; and books on plants and other species of wildlife, including a series of conservation action plans for threatened species.

Other notable IUCN works include *World Conservation Strategy: Living Resources Conservation for Sustainable Development* and its successor document *Caring for the Earth—A Strategy for Sustainable Living*; and the *United Nations List of Parks and Protected Areas*. IUCN also publishes books and papers on regional conservation, habitat preservation, environmental law and policy, ocean ecology and management, and conservation and development strategies.

Ivory-billed woodpecker

The ivory-billed woodpecker (*Campephilus principalis*) is one of the rarest birds in the world and is considered by most authorities to be extinct in the United States. The last confirmed sighting of ivory-bills was in Cuba in 1987 or 1988. Though never common, the ivory-billed woodpecker was rarely seen in the United States after the first years of the twentieth century. Some were seen in Louisiana in 1942, and since then, occasional sightings have been unverified. Interest in the bird rekindled in 1999, when a student at Louisiana State University claimed to have seen a pair of ivory-billed woodpeckers in a **wilderness** preserve. Teams of scientists searched the area for two years. No ivory-billed woodpecker was sighted, though some evidence made it plausible the bird was in the vicinity. By mid-2002, the ivory-billed woodpecker's return from the brink of **extinction** remained a tantalizing possibility, but not an established fact.

The ivory-billed woodpecker was a huge bird, averaging 19–20 in (48–50 cm) long, with a wingspan of over 30 in (76 cm). The ivory-colored bills of these birds were prized as decorations by native Americans. The naturalist John James Audubon found ivory-billed woodpecker in swampy forest edges in Texas in the 1830s. But by the end of the nineteenth century, the majority of the bird's prime **habitat** had been destroyed by **logging**. Ivory-billed woodpeckers required large tracts of land in the bottomland cypress, oak, and black gum forests of the Southeast, where they fed off insect larva in mature trees. This **species** was the largest woodpecker in North America, and they preferred the largest of these trees, the same ones targeted by timber companies as the most profitable to harvest. The territory for breeding pairs of ivory-billed woodpeckers consists of about three square miles of undisturbed, swampy forest, and there was little prime habitat left for them after 1900, for most of these areas had been heavily logged. By the 1930s, one of the only virgin cypress swamps left was the Singer Tract in Louisiana, an 80,000-acre (32,375-ha) swathe of land owned by the Singer Sewing Machine Company. In 1935 a team of ornithologists descended on it to locate, study, and record some of the last ivory-billed woodpeckers in existence. They found the birds and were able to film and photograph them, as well as make the only sound recordings of them in existence. The Audubon Society, the state of Louisiana, and the U.S. **Fish and Wildlife Service** tried to buy the land from Singer to make it a refuge for the rare birds. But Singer had already sold timber rights to the land. During World War II, when demand for lumber was particularly high, the Singer Tract was leveled. One of the giant cypress trees that was felled contained the nest and eggs of an ivory-billed woodpecker. Land that had been virgin forest then became soybean fields.

Few sightings of these woodpeckers were made in the 1940s, and none exist for the 1950s. But in the early 1960s ivory-billed woodpeckers were reported seen in South Carolina, Texas, and Louisiana. Intense searches, however, left scientists with little hope by the end of that decade, as only six birds were reported to exist. Subsequent decades yielded a few individual sightings in the United States, but none were confirmed.

In 1985 and 1986, there was a search for the Cuban subspecies of the ivory-billed woodpecker. The first expedition yielded no birds, but trees were found that had apparently been worked by the birds. The second expedition found at least one pair of ivory-billed woodpeckers. Most of the land formerly occupied by the Cuban subspecies was cut over for sugar cane plantations by the 1920s, and surveys in 1956 indicated that this population had declined to about a dozen birds. The last reported sightings of the species occurred in the Sierra de Moa area of Cuba. They are still considered to exist there, but the health of any remaining individuals must be in question, given the **inbreeding** that must occur with such a low population level and the fact that so little suitable habitat remains.

In 1999, a student at Louisiana State University (LSU) claimed to have seen a pair of ivory-billed woodpeckers while he was **hunting** for turkey in the Pearl River **Wildlife Management** Area near the Louisiana-Mississippi border. The student, David Kulivan, was a credible witness, and he soon convinced ornithologists at LSU to search for the birds. News of the sighting attracted thousands of amateur and professional birders over the next two years. Scientists from LSU, Cornell University, and the Louisiana Department of **Wildlife** and Fisheries organized an expedition that included posting of high-tech listening devices. Over more than two years, no one else saw the birds, though scientists found trunks stripped of bark, characteristic of the way the ivory-billed woodpecker feeds, and two groups heard the distinct double rapping sound the ivory-billed woodpecker makes when it knocks a trunk. No one heard the call of the ivory-billed woodpecker, though this sound would have been considered definitive evidence of the ivory-billed woodpecker's existence. Hope for confirmation of Kulivan's sighting rested on deciphering the tapes made by a dozen recording devices. This was being done at Cornell University, and was expected to take years.

By mid-2002, the search for the ivory-billed woodpecker in Louisiana had wound down, disappointingly in-

conclusive. While some scientists remained skeptical about the sighting, others believed that the forest in the area may have regrown enough to support an ivory-billed woodpecker population. *See also* Deforestation; Endangered species; Extinction; International Council for Bird Preservation; Wildlife management

Izaak Walton League

In 1922, 54 sportsmen and sportswomen—all concerned with the apparent destruction of American fishing waterways—established the Izaak Walton League of America (IWLA). They looked upon Izaak Walton, a seventeenth-century English fisherman and author of *The Compleat Angler*, as inspiration in protecting the waters of America. The Izaak Walton League has since widened its focus: as a major force in the American **conservation** movement, IWLA now pledges in its slogan "to defend the nation's **soil**, air, woods, water, and wildlife."

When sportsmen and sportswomen formed IWLA approximately 70 years ago, they worried that American industry would ruin fishing streams. Raw sewage, soil **erosion**, and rampant **pollution** threatened water and **wildlife**.

Initially the League concentrated on preserving lakes, streams, and rivers. In 1927, at the request of President Calvin Coolidge, IWLA organized the first national **water pollution** inventory. Izaak Walton League members (called "Ikes") subsequently helped pass the first national water **pollution control** act in the 1940s. In 1969 IWLA instituted the Save Our Streams program, and this group mobilized forces to pass the groundbreaking **Clean Water Act** of 1972. The League did not only concentrate on the preservation of American waters, however. From its 1926 campaign to protect the black bass, to the purchase of a helicopter in 1987 to help game law officers protect waterfowl from poachers in the Gulf of Mexico, IWLA has also been instrumental in the preservation of wildlife. In addition, the League has fought to protect public lands such as the National Elk Refuge in Wyoming, the **Everglades National Park**, and the Isle Royale National Park.
